

THE BRITISH JOURNAL OF PSYCHIATRY

July 1986

Vol 149

19

ISSN 0007-1250

Published by authority of
The Royal College of Psychiatrists

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al.*, *British Medical Journal*, 7 May 1983, **286**, 1489-1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in *italic* and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form '(Smith, 1971)' or 'Smith (1971) showed that ...'

DURKHEIM, E. (1897) *Le Suicide*. Paris. Translated (1952) as *Suicide: A Study in Sociology*, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. *British Journal of Psychiatry*, **124**, 352-358.

RUTTER, M. TIZARD, J. & WHITMORE, K. (1970) *Education, Health and Behaviour*. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In *Pathology and Treatment of Sexual Deviation* (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80-110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180-210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

Index to Volume 149

PART I—SUBJECTS

Compiled by Stanley Thorley

Abbreviations: C—Correspondence, Other abbreviations CAMDEX, ECT, GHQ, HLA, PSE-ID, SOMA and SRQ-20 given in the Index

Abdomen: Abnormal illness behaviour and anxiety in acute non-organic abdominal pain; P R Joyce *et al* 57–62

Acidosis: Severe lactic acidosis following paraldehyde administration, Christine M Linter and Stephen P K. Linter (*Brief report*) 650–651

Adolescence: Assessing and treating attention deficit disorder in adolescents. The clinical application of a single-case research design; S P Kutcher 710–715

Affective disorders *see also* **Mood disorders:** The continuum of psychosis and its implication for the structure of the gene, T J Crow 419–429

Post-ECT blood pressure rise and its relationship to cognitive and affective change, M P O'Donnell and M. C T Webb 494–497

Conditioning and sensitisation in the longitudinal course of affective illness; Robert M. Post *et al* 191–201

Aged: The prognosis of depression in old age; R. C. Baldwin and D J Jolly 574–583

Computed tomographic density numbers: a comparative study of patients with senile dementia and normal elderly controls; J. Colgan *et al* 716–719

Comparison of the nutritional state of new and long-term patients in a psychogeriatric unit; A. Greer *et al* 738–741

Cognitive functioning in Parkinson's disease: in relation to prevalence of dementia and psychiatric diagnosis; J R Oyeboode *et al* 720–725

CAMDEX. A standardised instrument for the diagnosis of mental disorder in the elderly with special reference to the early detection of dementia; M Roth *et al* 698–709

Agoraphobia: Marital adjustment, intimacy and needs in female agoraphobics and their partners: a controlled study; W. A Arrindell and P. M. G Emmelkamp 592–602

Follow-up of agoraphobic patients treated with exposure *in vivo* or applied relaxation; L. Jansson *et al* 486–490

Akathisia: A controlled assessment of propranolol in the treatment of neuroleptic-induced akathisia, Leonard Adler *et al* 42–45

Alcohol drinking: Alcohol-related problems in ethnic minorities; Arpan Banerjee and S. S. Virdee (C) 383

At risk drinking; John A. Ewing (C) 521

Gamma glutamyl transpeptidase and mean corpuscular volume. their usefulness in the assessment of in-patient alcoholics; R W Latham 353–356

Alcoholism: Exposure to parental alcoholism during childhood and outcome in adulthood. a prospective longitudinal study, W. R. Beardslee *et al* 584–591

Alkalosis: Sodium bicarbonate abuse. a case report, S. M. J Linford and H. D. James (*Brief report*) 502–503

Alzheimer's disease: Computed tomographic density numbers. A comparative study of patients with senile dementia and normal elderly controls; J Colgan *et al* 716–719

Cognitive functioning in Parkinson's disease. in relation to prevalence of dementia and psychiatric diagnosis; J R. Oyeboode *et al* 720–725

Identical twins discordant for presenile dementia of the Alzheimer type, E. B Renvoize *et al* (*Brief report*) 509–512

Amitriptyline: A comparison of the antidepressant action of citalopram and amitriptyline; D. M. Shaw *et al* (*Brief report*) 515–517

Annotations: Long-term psychiatric patients in the community, K Jones *et al* 537–540

Parasuicide and unemployment; S. Platt 401–405

Adolf Meyer some recollections and impressions, J. Wortis 677–681

Anorexia nervosa, complications: A case of anorexia nervosa with Klinefelter's syndrome; C. G Hindler and D. L Norris (*Brief report*) 659–660

Physical illness. A risk factor in anorexia nervosa; G. C. Patton *et al* 756–759

Anorexia nervosa in a woman totally blind since the age of two; Joel Yager *et al* (*Brief report*) 506–509

Anorexia nervosa, psychology: 'Demand characteristics' in body-size estimation in anorexia nervosa; Linda Proctor and Stephen Morley 113–118

Anorexia nervosa and dysmorphobia. A case study, P Sturmey and P. D. Slade (*Brief report*) 780–782

Anorexia nervosa, physiopathology: The effects of weight change on the dexamethasone suppression test in depressed and anorexic patients; I. Schweitzer *et al* 751–755

Anticholinergic agents: Anticholinergic antiparkinson medication for neuroleptic-induced extrapyramidal side-effects; Som D. Soni and D. A W. Johnson (C) 386

Antidepressive agents: Post-traumatic stress disorder following combat exposure: clinical features and psychopharmacological treatment; A. Bleich *et al* 365–369

Lithium augmentation of tricyclics, Ernest P. Worrall (C) 520–521

Antidepressive agents, tricyclic: A survey of practising psychiatrists' views on treatment of the depressions; M. S. Armstrong and G. Andrews 742–750

Lithium augmentation of tricyclics; Ernest P. Worrall (C) 520–521

Antigens: HLA antigens in schizophrenia a family study; R. Chadda *et al* 612–615

Antiparkinson agents: Anticholinergic antiparkinson medication for neuroleptic-induced extrapyramidal side effects, Som D. Soni and D. A. W Johnson (C) 386

Anxiety disorders, aetiology: Panic attacks: new approaches to an old problem; M. G Gelder 346–352

Anxiety disorders, complications: Depression and anxiety in

- patients undergoing diagnostic investigations for head and neck cancers; A. D. M. Davies *et al* 491-493
- Abnormal illness behaviour and anxiety in acute non-organic abdominal pain; P. R. Joyce *et al* 57-62
- Relationship of anxiety and depression: a review of the literature; Chrissoula Stavarakaki and Beverley Vargo (*Review article*) 7-16
- Anxiety disorders, diagnosis:** The SOMA—a questionnaire measure of sexual anxiety; D. G. Patterson and E. C. O'Gorman 63-67
- Anxiety disorders, familial and genetic:** Genetics of fear and anxiety disorders; I. M. Marks (*Review article*) 406-418
- Anxiety disorders, physiopathology:** The dexamethasone suppression test in generalised anxiety disorder; E. E. Schweizer *et al* 320-322
- Anxiety disorders, therapy:** Applied relaxation training for generalised anxiety and panic attacks: the efficacy of a learnt coping strategy on subjective reports; N. Tarrier and C. J. Mann 330-336
- Appetite disorders:** Quetelet's index and appetite and weight change in the context of depression; Brian Harris *et al* (C) 522-523
- Art therapy:** Art group psychotherapy in a psychiatric day unit; Charles Lund *et al* (*Brief report*) 512-515
- Asylum reports:** Lectures for nurses (Dr Hitchcock); Henry Rollin (*A hundred years ago*) 799
- Holloway's Charity; Henry Rollin (*A hundred years ago*) 387
- Attachment dynamic:** The attachment dynamic in adult life; D. H. Heard and B. Lake 430-438
- Attention deficit disorder:** Assessing and treating attention deficit disorder in adolescents. The clinical application of a single-case research design; S. P. Kutcher 710-715
- Australia:** A survey of practising psychiatrists' views on the treatment of schizophrenia; S. Andrews *et al* 357-364
- A survey of practising psychiatrists' views on treatment of the depressions; M. S. Armstrong and G. Andrews 742-750
- Autism:** Autism and autistic-like conditions in Swedish rural and urban areas: a population study; Suzanne Steffenberg and Christopher Gillberg 81-87
- relationship to cognitive and affective change; M. P. O'Donnell and M. G. T. Webb 494-497
- Body image:** 'Demand characteristics' in body-size estimation in anorexia nervosa; Linda Proctor and Stephen Morley 113-118
- Body size estimation in bulimia; Andrew M. Whitehouse *et al* 98-103
- Books reconsidered:** *Dementia praecox oder die Gruppe der Schizophrenien*; Eugen Bleuler; Manfred Bleuler and Rudolf Bleuler 661-664
- Sanity, Madness and the Family*; R. D. Laing and A. Esterson, Anthony S. David 379-381
- Psychotherapy by reciprocal inhibition*; Joseph Wolpe; Stuart Lieberman 518-519
- Brief reports:** Multiple pathology in a mentally handicapped individual; E. Akuffo *et al* 377-378
- Changes in mood, appetite and psychomotor retardation in depressed patients given ECT; M. Browning and P. J. Cowen 371-373
- Suicide among schizophrenics; a comparison of attempters and completed suicides; Robert E. Drake *et al* 784-787
- Depression in schizophrenia: a study of prevalence and treatment; R. Elk *et al* 228-229
- Treatment of depression in Huntington's disease with monoamine oxidase inhibitors; M. F. Ford 654-656
- Childhood encopresis extending into adult life; A. M. Frazer and D. C. Taylor 370-371
- Electro-oculogram changes at the switch in a manic-depressive patient; S. M. Hanna *et al* 229-232
- Seasonal hypomania in a patient with cold urticaria; N. S. Harvey and W. I. Mikhail 238-241
- A case of anorexia nervosa with Klinefelter's syndrome; C. G. Hindler and D. L. Norris 659-660
- The Life Satisfaction Index—well-being: its internal reliability and factorial composition; O. James *et al* 647-650
- Paranoid reaction and underlying thyrotoxicosis; S. H. Kamlana and L. Holms 376-377
- Trazodone-induced mania; Haim Y. Knobler *et al* 787-789
- Priapism and psychotropic medication; J. Kogeorgos and C. de Alwis 241-243
- Sodium bicarbonate abuse: a case report; S. N. J. Linford and H. D. James 501-503
- Severe lactic acidosis following paraldehyde administration; Christine M. Linter and Stephen P. K. Linter 650-651
- Munchausen's syndrome and drug dependence; M. London and K. Ghaffari 651-654
- Art group psychotherapy in a psychiatric day unit; Charles Lund *et al* 512-515
- A clinical study of Gilles de la Tourette's syndrome in Korea; Sung Kil Min and Helen Lee 644-647
- Clopenthixol decanoate in the management of aggressive mentally handicapped patients; T. J. J. Mlele and Yvonne V. Wiley 373-376
- Koro in an Israeli male; Ilan Modai *et al* 503-506
- Severe self-mutilation among Kenyan psychotics; E. A. P. Mulaka and M. Dhadphale 778-780
- A study of violent behaviour among in-patients in a psychiatric hospital; M. Pearson *et al* 232-235
- Bayes theorem:** The formation of maintenance of delusions: a Bayesian analysis; D. R. Hersley and P. A. Garety 51-56
- Behaviour therapy:** Follow-up of agoraphobic patients treated with exposure in vivo or applied relaxation; L. Jansson *et al* 486-490
- Bereavement:** Mania following bereavement; J. A. G. Watt (C) 244. Paul Bridges (C) 244. Lisette Lovett (C) 123. Paul V. Gill (C) 123-124
- Bipolar disorder:** Disturbance of water and sodium in a manic depressive illness; J. L. Crammer 337-345
- Electro-oculogram changes at the switch in a manic-depressive patient; S. M. Hanna *et al* (*Brief report*) 229-232
- Blindness:** Anorexia nervosa in a woman totally blind since the age of two; Joel Yager *et al* (*Brief report*) 506-509
- Blood pressure:** Post-ECT blood pressure rise and its

- The influence of psychological factors on the opiate withdrawal syndrome; C. T. Phillips *et al* 235-238
- Identical twins discordant for presenile dementia of the Alzheimer type; E. B. Renvoize *et al* 509-512
- A case of resistant schizophrenia; J. E. Roberts *et al* 789-793
- A comparison of the antidepressant action of citalopram and amitriptyline; D. M. Shaw *et al* 515-517
- Anorexia nervosa and dysmorphobia. A case study; P. Sturmer and P. D. Slade 780-782
- Autocastration and biblical delusions in schizophrenia, Arnold C. Waugh 656-659
- Organic factors in catatonia; James A. Wilcox and Henry A. Nasrallah 782-784
- Anorexia nervosa in a woman totally blind since the age of two, Joel Yager *et al* 506-509
- Briquet syndrome:** A follow-up and family study of Briquet's syndrome; S. B. Guze *et al* (*Symposium on hysteria*) 17-23
- Bulimia:** Relationship of mood alterations to bingeing behaviour in bulimia; W. H. Kaye *et al* 479-485
- Body size estimation in bulimia; Andrew M. Whitehouse *et al* 98-103
- CAMDEX** (Cambridge Mental Disorders of the Elderly Examination): CAMDEX. A standardised instrument for the diagnosis of mental disorder in the elderly with special reference to the early detection of dementia; M. Roth *et al* 698-709
- Cancer:** Psychosocial effects of mastectomy: is it due to mastectomy or to the diagnosis of malignancy? T. T. Alagaratnam and N. Y. T. Kung 296-299
- Depression and anxiety in patients undergoing diagnostic investigations for head and neck cancers, A. D. M. Davies *et al* 491-493
- Carpal tunnel syndrome:** Lithium induced hypothyroidism presenting with carpal tunnel syndrome; Kenneth A. Wood and Robin J. Jacoby (C) 386-387
- Catatonia:** Organic factors in catatonia; James A. Wilcox and Henry A. Nasrallah (*Brief report*) 782-784
- Child behaviour disorders:** Behaviour problems in retarded children with special reference to Down's syndrome; Ann Gath and Dianne Gumley 156-161
- Childhood hyperactivity; E. A. Taylor (*Review article*) 562-573
- Conduct disorder and hyperactivity I. Separation of hyperactivity and antisocial conduct in British child psychiatric patients; E. Taylor *et al* 760-767
- Conduct disorder and hyperactivity: II. A cluster analytic approach to the identification of a behavioural syndrome; E. Taylor *et al* 768-777
- Child development disorders:** Exposure to parental alcoholism during childhood and outcome in adulthood: a prospective longitudinal study; W. R. Beardslee *et al* 584-591
- Citalopram:** A comparison of the antidepressant action of citalopram and amitriptyline, D. M. Shaw *et al* (*Brief report*) 515-517
- Clopenithiol:** Clopenithiol in aggressive mentally handicapped patients; N. Bourgas *et al* (C) 795
- Clopenithiol decanoate in the management of aggressive mentally handicapped patients; T. J. J. Mlele and Yvonne V. Wiley (*Brief report*) 373-376
- Cognition disorders:** Macrocytosis and cognitive decline in Downs' syndrome; D. M. Hambidge (C) 797-798
- Post-ECT blood pressure rise and its relationship to cognitive and affective change, M. P. O'Donnell and M. G. T. Webb 494-497
- Cognitive functioning in Parkinson's disease: in relation to prevalence of dementia and psychiatric diagnosis; J. R. Oyeboode *et al* 720-725
- Orofacial dyskinesia, cognitive function and medication; P. Thomas and R. McGuire 216-220
- Combat disorders:** Post-traumatic stress disorder following combat exposure: clinical features and psychopharmacological treatment; A. Bleich *et al* 365-369
- Community mental health services:** Community care of the acutely mentally ill; John Hoult (*First Upjohn lecture 1985*) 137-144
- Long-term psychiatric patients in the community; K. Jones *et al* (*Annotation*) 537-540
- Providing information to relatives about schizophrenia: some comments; N. Tarrier and C. Barrowclough 458-463
- Community care of the acutely mentally ill; T. H. Turner (C) 799
- Cost of community psychiatry; P. Tyrer *et al* (C) 795-796
- A haven for the severely disabled within the context of a comprehensive psychiatric community service; J. K. Wing and R. Furlong 449-457
- Conditioning:** Conditioning and sensitisation in the longitudinal course of affective illness; Robert M. Post *et al* 191-201
- Conduct disorders, child:** Conduct disorder and hyperactivity: I. Separation of hyperactivity and antisocial conduct in British child psychiatric patients, E. Taylor *et al* 760-767
- Conduct disorder and hyperactivity: II. A cluster analytic approach to the identification of a behavioural syndrome; E. Taylor *et al* 768-777
- Conflict:** Inter-generational conflict and psychiatric symptoms; M. F. El-Islam *et al* 300-306
- Conversion disorder:** *see also* **Hysteria:** Is hysteria (conversion reaction) still alive?; Abraham Verghese (C) 120
- Cross-cultural comparison:** Mental illness among immigrant minorities in the United Kingdom; M. London (*Review article*) 265-273
- Emotional attitudes and direct communication in the families of schizophrenics. a cross-national comparison, A. M. Strachan *et al* 279-287
- Day care:** Art group psychotherapy in a psychiatric day unit, Charles Lund *et al* (*Brief report*) 512-515
- Delusions:** ECT as a contributor to the production of delusional misidentification; Kay Callender (C) 520
- The formation of maintenance of delusions: a Bayesian analysis; D. R. Hemsley and P. A. Garety 51-56

- Autocastration and biblical delusions in schizophrenia; Arnold C. Waugh (*Brief report*) 656-659

- Dementia, physiopathology:** Computed tomography density numbers. A comparative study of patients with senile dementia and normal controls; J. Colgan *et al* 716-719
- Subcortical dementia. neuropsychology, neuropsychiatry and pathophysiology; J. L. Cummings (*Review article*) 682-697
- Comparison of the nutritional state of new and long-term patients in a psychogeriatric unit; A. Greer *et al* 738-741
- The role of zinc in senile dementia; C. Kenn and E. Gibb 221-223
- Dementia, psychology:** Cognitive functioning in Parkinson's disease. in relation to prevalence of dementia and psychiatric diagnosis; J. R. Oyebode *et al* 720-725
- Depressive disorder, classification:** Anhedonic depression; S. K. Chaturvedi (C) 521-522
- Endogenous subtype of depression, Jonathan W. Stewart (C) 245-246
- Depressive disorder, complications:** Depression and anxiety in patients undergoing diagnostic investigations for head and neck cancers; A. D. M. Davies *et al* 491-493
- Depression in schizophrenia. a study of prevalence and treatment, R. Elk *et al* (*Brief report*) 228-229
- Treatment of depression in Huntington's disease with monoamine oxidase inhibitors; M. F. Ford (*Brief report*) 654-656
- Depression in schizophrenia: prevalence and treatment; James Graham (C) 668
- Depression in schizophrenia, Naomi Richman (C) 797
- Depression in mentally handicapped patients; diagnostic and neuroendocrine evaluation; L. Sireling 274-278
- Relationship of anxiety and depression. a review of the literature; Chrissoula Stavarakaki and Beverley Vargo (*Review article*) 7-16
- Depressive disorder, diagnosis:** An American validation study of the Newcastle diagnostic scale. I Relationship with the Dexamethasone Suppression Test; M. Zimmerman *et al* 627-630
- Depressive disorder, occurrence:** Psychosocial risk factors and urban/rural differences in the prevalence of major depression; B. A. Crowell Jr *et al* 307-314
- Depressive disorder, physiopathology:** Quetelet's index and appetite and weight change in the context of depression; Brian Harris *et al* (C) 522-523
- Monitoring of long-term motor activity in depressed patients, S. Royant-Parola *et al* 288-293
- The effects of weight change on the dexamethasone suppression test, in depressed and anorexic patients, I. Schweitzer *et al* 751-755
- Depressive disorder, prognosis:** The prognosis of depression in old age; R. C. Baldwin and D. J. Jolley 574-583
- Depressive disorder, therapy:** A survey of practising psychiatrists' views on treatment of the depressions; M. S. Armstrong and G. Andrews 742-750
- Changes in mood, appetite and psychomotor retardation in depressed patients given ECT; M. Browning and P. J. Cowen (*Brief report*) 371-373
- A comparison of the antidepressant action of citalopram and amitriptyline, D. M. Shaw *et al* (*Brief report*) 515-517
- Dexamethasone:** Dexamethasone suppression test; Malcolm Bruce (C) 120
- The dexamethasone suppression test in generalised anxiety disorder; E. E. Schweizer *et al* 320-322
- The effects of weight change on the dexamethasone suppression test in depressed and anorexic patients, I. Schweitzer *et al* 751-755
- Depression in mentally handicapped patients. diagnostic and neuroendocrine evaluation; L. Sireling 274-278
- An American validation study of the Newcastle diagnostic scale. I Relationship with the Dexamethasone Suppression Test; M. Zimmerman *et al* 627-630
- Disipal in the neuroleptic syndrome:** Anticholinergic antiparkinson medication for neuroleptic-induced extrapyramidal side effects; Som D. Soni and D. A. W. Johnson (C) 386
- Doctors:** Suicide in young doctors; J. C. Richings *et al* 475-478
- Down's syndrome:** Behaviour problems in retarded children with special reference to Down's syndrome; Ann Gath and Dianne Gumley 156-161
- Family background of children with Down's syndrome and of children with a similar degree of mental retardation; Ann Gath and Dianne Gumley 161-171
- Macrocytosis and cognitive decline in Down's syndrome; D. M. Hambridge (C) 797-798
- Drug dependence:** Munchausen's syndrome and drug dependence; M. London and K. Ghaffari (*Brief report*) 651-654
- Drugs see Anticholinergic, Antidepressive and Antiparkinson agents, Monoamine oxidase inhibitors, Neuroleptics and Tranquilizing agents, major**
- See Alcohol, Amitriptyline, Citalopram, Clopenthixol decanoate, Dexamethasone, Disipal, Fluphenazine, Gamma-glutamyl transferase, Gluten, Ibuprofen, Lithium, Methylphenidate, Orphenadrine, Papaverine, Paraldehyde, Phenoxybenzamine, Piroxicam, Procyclidine, Propranolol, Pseudoephedrine, Sodium bicarbonate, Thioridazine, Trazodone and Zinc**
- Drug therapy see Medication:**
- Dyskinesia, tardive:** Tardive dyskinesia and Parkinsonism; Ferni Oyebode and Hamish McClelland (C) 122-123.
- Carlos Garcia Ribera (C) 665-666
- The Nithsdale schizophrenia survey V. 3½-year follow-up tardive dyskinesia, A. D. T. Robinson and R. G. McCreadie 621-623
- Orofacial dyskinesia, cognitive function and medication; P. Thomas and R. McGuire 216-220
- Late onset involuntary movements in chronic schizophrenia: relationship of 'tardive' dyskinesia to intellectual impairment and negative symptoms; J. L. Waddington and H. A. Youssef 616-620
- Dysmorphobia:** Anorexia nervosa and dysmorphobia; P. Sturmey and P. D. Slade (*Brief report*) 780-782
- Dystonia:** Tardive dystonia and Pisa syndrome; Shekhar Saxena (C) 524

- ECT (Electroconvulsive therapy):** A survey of practising psychiatrists' views on treatment of the depressions; M. S. Armstrong and G. Andrews 742-750
- Patients who break their fast before ECT;** G. E. Bernos and G. Sage 294-295
- Changes in mood, appetite and psychomotor retardation in depressed patients given ECT;** M. Browning and P. J. Cowen (*Brief report*) 371-373

Tranquillisers

Social, psychological,
and clinical perspectives

**Edited by JONATHAN GABE,
and PAUL WILLIAMS**

There is a large literature on tranquilliser use but much of it is exclusively concerned with pharmacological issues. The exploration of social aspects has been relatively neglected. In recognition of the pressing need to examine tranquilliser use in a much broader perspective, this volume brings together social, psychological, and clinical viewpoints.

Mental Health Practices in Primary Care Settings

An annotated bibliography

Edited by GREG WILKINSON

This unique annotated bibliography deals with selected English and foreign language publications between 1977 and 1985. The book examines the doctor—or primary care physician—in his influential position as 'gate-keeper' between patient and the formal psychiatric community. It will prove an essential reference and research source to anyone concerned with mental health policy and practice.

448 pages Hardback 0 422 60180 2 £27.50

Crisis, Health, and Medicine

A social critique

VICENTE NAVARRO

In an incisive analysis of the crisis within the western system of medicine, Vicente Navarro provides a critique of the current dominant interpretations of health and medicine. He convincingly shows how the social, political, and economic forces that shape the nature of western society also shape the nature, organization, and ideology of medicine.

Basic Psychiatry (MRCPSYCH Part I Examination)

Weekly half-day lectures with additional study days will be held at Guy's Hospital commencing in October 1986 and continuing until July 1987.

The course is suitable for candidates preparing for the revised first part of the examination for Membership of the Royal College of Psychiatrists. Theoretical materials will be supplemented by clinical discussion. The course includes science basic to psychiatry, psychopathology, and interviewing and clinical assessment.

Fee £250 payable on registration. Candidates should apply to the Postgraduate Secretary, Division of Psychiatry, U.M.D.S., Guy's Hospital, London, SE1 9RT (Tel: 01-407 7600 ext. 3109).

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

GRUNE & STRATTON LTD

THE SCIENTIFIC PRINCIPLES OF PSYCHOPATHOLOGY

Edited by
P MCGUFFIN
M SHANKS
R HODGSON

This book is aimed primarily at psychiatrists and clinical psychologists in training and will more than adequately cover their professional and examination needs regarding the scientific principles of their subject. Aspects of recent research in the biological, social and psychological sciences which are most relevant to the practising clinician are also provided in a critical, comprehensive but readable style, making this book a useful reference work for other physicians and professionals from allied disciplines.

1984 800pp £35.00/\$60.00 ISBN 0 8089 1667 X

ESSENTIALS OF POSTGRADUATE PSYCHIATRY, 2nd Edition

Edited by
PETER HILL
ROBIN MURRAY
ANTHONY THORLEY

Reviews of 1st edition

"... Precision, clarity and scholarship characterise this first textbook of Psychiatry to emerge from the world renowned Maudsley in London."

— American Journal of Psychiatry

"... There are no other serious British competitors... The book under review provides the most comprehensive, balanced and up-to-date review of knowledge in psychiatry today."

— The Lancet

The second edition of this successful textbook provides extensive coverage of the richness and variety of psychiatry while at the same time integrating psychiatric research findings into a wider body of clinical knowledge. Written by individuals associated with the world renowned Maudsley Hospital *Essentials of Postgraduate Psychiatry* provides a more up-to-date and scientific volume than any existing psychiatric text.

Different Causative Factors in Different Forms of Schizophrenia

KARL LEONHARD

Definite conclusions about the origin of schizophrenia concerning hereditary as well as psychosocial factors can be obtained when different forms of schizophrenia are investigated separately.

We still know much too little about schizophrenia. This applies particularly to its origin. Being an older psychiatrist, I am well aware of the extensive and intensive research work performed since the time of Kraepelin and Eugen Bleuler. Unfortunately, though, there has not been much progress. After the First World War, when Kraepelin and Bleuler were still alive, most psychiatrists believed they could regard schizophrenia as an inherited disease. This was generally accepted in Germany where the doctrine of Rüdin dominated research on the genetics of schizophrenia. However, he was influential not only in Germany, but in many other countries, too. For example, Kallman in the USA worked with Rüdin for several years. Rüdin and his pupils knew the extent of the gap which existed between practical observations and theoretical expectations according to Mendel's laws, and tried again and again to bridge the gap. They did so in vain. Many hypotheses were established. Some authors suggested a dominant mode of inheritance, others suggested a recessive heritability. Neither of the contrasting views held up to scrutiny. Nevertheless the belief that heredity was crucial continued, and this had disadvantageous effects on psychiatric research for, in consequence, the existence of other causative factors was completely disregarded. The result in Germany was horrible: from the alleged exclusive heritability of the endogenous psychoses Hitler derived the foundation of his laws by which he forcibly sterilised and even killed so many patients.

Partly as a reaction to these crimes, afterwards heredity was disregarded. Psychoanalytical and psychosocial theories now became completely dominant. When the North-Americans came to Germany

after the Second World War they attempted to convince us that schizophrenia would occur if a baby had been frustrated and had not been given his mother's milk in good time. This was the era of the "schizophrenogenic mother". Such psychoanalytical theories could not be upheld for long, though some of the psychosocial views arising subsequently were psychoanalytically oriented. The theories established by Lidz, Bateson, Wynne, Singer are generally known and very often cited. There has been much discussion of these theories, but after some attempts at replication, again, they did not hold up. Now many psychiatrists have returned to genetic theories and regard inheritance as decisive in causing schizophrenia. You can again find attempts at revealing a Mendelian mode of genetic transmission though all such attempts failed as long as 50 years ago. The wheel has turned full circle.

In my opinion, this regrettable state is due to the fact that schizophrenia is taken as a single entity, even though Eugen Bleuler did not speak of schizophrenia—but of "a group of schizophrenias". Indeed, definite results can be obtained concerning heredity as well as psychosocial factors when different forms of schizophrenia are investigated separately.

During the 15 years after I retired, I was able to devote myself entirely to research and was in a position to complement our knowledge of schizophrenia (through clinical and genetic examinations of more than 1400 patients). The classification on which my investigations are based have been made known in the English language from the publications by Fish, (1958, 1962, 1964), Astrup (1962), Perris (1960, 1974); and as far as my differentiation between the monopolar and the bipolar depressions is concerned, from many other publications. My classification has been presented in detail by Ban

*Opening lecture delivered at the Regional Symposium of the World Psychiatric Association, Rio de Janeiro, April 18-21, 1985

et al (1981). And my book *The Classification of Endogenous Psychoses* has also appeared in English (Leonhard, 1979).

Here, the "systematic" schizophrenias correspond to the "typical" schizophrenias, especially described by the late Japanese psychiatrist, Mitsuda. They constitute the "nuclear" schizophrenias and in almost all cases run an insidiously progressive course. The "non-systematic" schizophrenias correspond to the "atypical" schizophrenias and are predominantly remitting or even periodic. Also in their symptoms pattern they differ from the systematic forms (see Fish, 1958; 1962).

Among the endogeneous psychoses, 5 groups have to be differentiated. First: the systematic schizophrenias; second: the non-systematic schizophrenias; third: the cycloid psychoses must be separated from schizophrenia. They never lead to mental deterioration, and each phase is followed by complete recovery. The fourth and fifth groups comprise monopolar depressions and manic-depressive illness. These two forms are now generally accepted. In my opinion, there are also monopolar manias, the existence of which is mostly denied. The schizo-affective psychoses are not among the five groups. I cannot regard them as an independent group because their prognosis is indefinite. Some of these with schizo-affective psychoses recover from every phase and, in my opinion, have cycloid psychoses. Others tend to deteriorate, more and more, from shift to shift, and belong to the non-systematic schizophrenias. Whether the one psychosis is present or the other, can be identified from the distinct psychiatric picture. Thus the schizo-affective psychoses have to be separated into these two different groups (Leonhard, 1983).

The five groups of endogenous psychoses, especially the two schizophrenias and the cycloid psychoses, have quite different aetiologies. First, different inheritance: 604 systematic schizophrenics whom we examined had 1403 siblings—only 29 of them, i.e., 2.1% were ill; our 429 non-systematic schizophrenias had 744 siblings—117, i.e., 15.7% were ill. In these figures Weinberg's correction has been used. Individuals under 17 years have not been counted, individuals aged from 17 to 40 have been counted half, individuals over 40 have been fully counted.

So, in the severest forms an extremely small family history of psychotic disorder is found. In these forms psychosocial factors must be looked for. Genetic loading is also low in the cycloid psychoses, but not to so large an extent as in the systematic schizophrenias. Our 221 cycloid psychotic patients had 393 siblings—16 of them, i.e., 4.1 per cent were

ill. Thus family history of psychotic disorder is low in the severest as well as in the mildest forms of the so-called schizophrenias. It is striking that our absolute figures differ so greatly in size. This is due to the fact that we undertook our investigations in hospitals where chronic patients were prevalent. In hospitals with predominantly acute psychoses the cycloid forms are as common as the systematic and as the non-systematic schizophrenias.

I found a low hereditary loading in the systematic schizophrenias when I started my investigations into the endogenous psychoses at the beginning of my psychiatric life; but over the years I could not detect any external influences. On the basis of the examination of twins I ultimately succeeded. I have personally examined 45 monozygotic twins and 25 ill co-twins, and, in addition, 47 dizygotic twins. Among the latter all forms of endogenous psychoses occurred. By contrast, in the monozygotic twins systematic schizophrenias were completely lacking. This was extremely surprising and totally unexpected. The finding applied to the 45 index-twins and the 25 ill co-twins as well. It seems that we encountered an external factor involved in the causation of the systematic schizophrenias. The finding gives rise to the conclusion that identical twin-ship can protect the individual from falling ill with this special kind of schizophrenia. How can this be explained? I think we must give consideration to the fact that monozygotic twins being identical in their somatic and psychical constitution understand one other to so complete a degree that they cannot become entirely autistic. And we know since Eugen Bleuler that autism is a central symptom of schizophrenia. The close communication with the co-twin seems to compensate sufficiently for the little contact which may exist with other people. Following our explanation we can assume that, in turn, lack of communication, lacking even one single friend, can encourage the development of schizophrenia.

Our findings contradict the psychosocial theory according to which identical twins have difficulties in finding their identity and therefore both of them are prone to the development of schizophrenia. On the contrary they are liable to schizophrenia to a lesser degree. However, I must add that other forms of endogenous psychoses accumulate in twins. I will return to this later.

Many authors have discussed the significance of isolation and lack of communication in the origin of schizophrenia. They could not obtain definite results as they took schizophrenia as a unity. Moreover, they predominantly deal with the concept isolation as it is present in adults, whereas, according to our observations lack of communi-

cation is only predisposing towards schizophrenia when operating in childhood.

Communication between twins is psychosocial in nature, lack of communication is also a psychosocial factor; but the effect on the patient seems to be organic, for the systematic schizophrenias, which in most cases terminate in serious deterioration, certainly have an organic basis. This kind of influence is possible in childhood and adolescence when the nervous system has not matured. Isolation can result in such consequences. Let me quote the brain pathologist Seitelberger (1980):

"The maturation not only of the sensory system and the motor apparatus, but also of all parts of the brain which of necessity work as a unit, is dependent on the external demands made. It has been shown that systems which are kept from functioning by means of isolation do not attain their morphological maturation and remain non-functional. On exposure to external influences after the critical maturation period has been passed the deficit can no longer be compensated. The processes of morphological differentiation are to a continually decreasing degree demonstrable in the nerve-cells and their associative fibres until the end of the second decade of life. So, these changes accompany the processes of mental maturation in the individual."

So, the organic effect of isolation can be demonstrated morphologically. Such an influence was observed in the children described by Spitz (1945) in whom lack of communication resulted in severe somatic disturbances; many of the children died though they had been well fed, and children who survived became severely mentally retarded.

In the cycloid psychoses nothing is suggestive of an organic basis. Accordingly their origin has nothing in common with that of the systematic schizophrenias. As regards heredity, surprising results appeared when we differentiated between two sub-forms, anxiety-happiness-psychosis and motility psychosis. In both these cases the family history of psychiatric disorder is small, in siblings 4.1% and 4.2% respectively. Nevertheless the concordance rates in identical twins differ greatly. Of our six pairs with anxiety-happiness-psychosis only one was concordant; this conforms with the low hereditary loading. But of our 11 pairs with motility psychosis no less than 9 had also fallen ill. From this latter result the geneticists would derive an extremely great heritability which, in fact, does not exist. In motility psychosis no more siblings were ill than in anxiety-happiness-psychosis. In the parents, there were fewer ill individuals in motility psychosis (5.1% versus 6.3%). The old rule established by Galton and thereafter being an important guideline for geneticists, loses its validity with the cycloid psychoses. Indeed, in spite of the extraordinarily high concordance rate in identical twins the heritability of motility psychosis is low. I will give an interpretation of this finding later. In our twins with monopolar depression the concordance rate was also high though relatively few parents and siblings were ill.

Alarmed by the finding in our twin studies we focused on sibships, their sizes, and the position of the patient

among the siblings. In this regard many investigations have been carried out by other authors, again considering schizophrenia as a whole. Various and conflicting results have been obtained. We again differentiated between different forms and many definite results became apparent. I came to the conclusion that siblings by mutual influences contribute to the development of the individual in childhood and adolescence and do so not only psychologically but also biologically. On this basis the influence of siblings can prevent or, on the contrary, encourage the appearance of schizophrenia. Childhood friends may play the same role as siblings.

Let me consider cycloid psychoses in this respect. Striking results appeared when I compared motility psychosis with another sub-form, confusion psychosis. There were relatively many siblings in the first illness and relatively few in the latter. However, the difference applied only to the older siblings. In our series, 100 patients with motility psychosis had 172 older siblings, and 100 patients with confusion psychosis had only 78. The number of younger siblings differed little (127:108). This latter difference is not statistically significant. I conclude that the alleged mutual influence of siblings occurs in the first years of life when younger siblings either do not exist or are so helpless that they cannot exert any influence on older siblings. This fits into the psychoanalytic view about the first years of life. I do not discuss the question why it applies just to these cycloid psychoses whereas in other endogenous forms the external influence is operating during later childhood. And I am not able to answer the question why the existence of many siblings contributes to the origin of motility psychosis and the lack of siblings to the origin of confusion psychosis. However, I point out an interesting parallel. Motility psychosis often occurs in twins. Of our 92 twins 22 (11 monozygotic, 11 dizygotic) suffered from this cycloid psychosis. Perhaps the close relationship existing in twins corresponds to the increased relationship resulting from a greater number of siblings and thus either condition enhances the morbidity risk for motility psychosis. Probably siblings can stimulate each other too much so that the nervous system can be overstrained.

At this point I should like to return to the question of why there are some different concordance rates in identical twins with anxiety-happiness-psychosis and, on the other hand, with motility psychosis. In the latter case the influence is mutually exerted, both twins are involved. In contrast, in anxiety-happiness-psychosis there is only a one-sided influence. From other findings, I came to the conclusion that tensions in childhood can create a disposition to anxiety-happiness-psychosis and jealousy of the inferior twin toward the partner can represent the basis of such tensions. In this case for the dominant twin there is no reason to be jealous and he will remain well. So the influence is one-sided. One of our identical twin pairs gives support to this interpretation. The index twin sustained a fracture of the vertebral column at the age of 12 and had to lie on a plaster bed for several years. Moreover her father favoured the co-twin. The mother tried to compensate for this, but the father was entirely dominating in the family so that his affection was of greater importance than that of the mother. The index-twin fell ill with anxiety-happiness-

psychosis while the co-twin remained healthy. She became jealous of her sister who was somatically healthy and was favoured by the father. She continuously fought her sister in an attempt to gain ascendancy.

Concerning the non-systematic schizophrenias, I must first point out the high hereditary loading. For one of these forms (periodic catatonia) I could suggest a dominant inheritance pattern. The gap existing between the Mendelian estimates and the empirical findings could be bridged by examining many of the allegedly healthy parents. In fact, many of them were seriously abnormal. We found that in periodic catatonia 22.0% of the parents were ill and approximately as many were abnormal to a high degree. Thereby the Mendelian estimate is nearly matched. However, when the psychosis manifests itself completely external factors must operate in addition.

We found that periodic catatonics have relatively few siblings. This contrasts with the findings in motility psychosis though there are certain similarities between the two psychoses. As in periodic catatonia, many of the parents were psychotic—the time for propagation was possibly limited. But it turned out that healthy parents had only a few more children than psychotic parents. It seems then that the manifestation of periodic catatonia decreases when many siblings exist. Direct evidence of this emerged when we examined how many ill siblings came from large sibships and how many from small sibships. Many more ill siblings were found in small sibships. The figures were 29.4:17.6 in relation to the number of healthy siblings.

Some families seemed to confirm that large sibships can prevent the manifestation of periodic catatonia. This applied to the following family which contained no less than 15 siblings. Two of them had children with periodic catatonia. Thus it can be seen that the hereditary predisposition for periodic catatonia existed in the family. Nevertheless all of the 15 siblings remained healthy. I think the large sibship protected them from falling ill.

What factor might be operating to produce this effect? I suggest that a child feels protected and sheltered when living in companionship with several siblings so that he is more likely to grow up free from anxieties. Such a view fits into some psychosocial assumptions. With respect to periodic catatonia, I can confirm this view. One of our observations seems at first to contradict our interpretation, but on the contrary it supports it when the family is more completely examined. Of 10 siblings, no less than four fell ill with periodic catatonia. The existence of so many children was by no means preventive. The Mendelian estimates were nearly reached; half of the children are expected to fall ill in a dominant inheritance.

But let me describe this family thoroughly: the father was an excessive drinker and most of the time he used to sit in pubs. He used to beat his children brutally. When a little child cried he beat him or he beat an older child whom he declared responsible for the crying. As soon as the father returned home the whole family became silent; and the children made themselves scarce. The mother tried to intervene, but was rejected and was often beaten herself. The children in this family grew up under continuous anxieties; the large sibship could not prevent this.

Another psychosocial theory was not confirmed. Some

psychiatrists believe that the abnormal behaviour of a schizophrenic mother can cause an illness in the child. The assumption again has been related to schizophrenia as a whole, but periodic catatonia represents the schizophrenic form in which most frequently parents as well as children are ill, so that the validity of the theory can be tested. Heston (1966) opposed the assumption after he had examined children of schizophrenic mothers who had grown up in a home. Our patients who had catatonic mothers did not have more ill siblings than patients with healthy mothers; on the contrary they had fewer. But in spite of this the index-patients relatively often had psychotic mothers, when there was no older sister. This is astonishing and indicates that an older sister is qualified or even biologically designed to replace the mother who has been lost or is mentally incapable. Now we understand why index-patients with ill parents have not more, but fewer ill siblings than index-patients with healthy parents. In the first case the siblings could remain healthy because most of them had older sisters, for example the index individual who later fell ill. In the event of a healthy mother, the presence or absence of an older sister is without significance. If we are surprised that the existence of an older sister can reduce the risk for periodic catatonia we must remember how unselfishly older sisters often devote themselves to the care of younger siblings after the mother has been lost. According to my findings the above psychosocial theory must be corrected as follows: it is not the abnormal behaviour of a psychotic mother, but loss of the mother in association with absence of an older sister which may be important. However, in any case, the external influence does not cause periodic catatonia which is a hereditary illness, but only increases its manifestation.

Another non-systematic schizophrenia with a hereditary basis is affective paraphrenia. In this psychosis a recessive mode of inheritance is suspected because, on the one hand, we found relatively many ill siblings (13.3%) and very few ill parents (2.2%). On the other hand, I could describe a large family containing 18 affective paraphrenics of whom no less than 13 descended from consanguineous marriages. Both these findings suggest a recessive inheritance. The probability of manifestation is increased in females; in our series 95 affective paraphrenics were females and only 25 males. As far as affective form of paraphrenia is concerned, we may assume that affective lability, representing a personality trait of the women, can promote the onset of the illness.

As regards psychosocial factors, some psychiatrists believe that children become liable to schizophrenia if they cannot acquire the role belonging to them by age and sex. In most forms of schizophrenia I did not find anything fitting this theory, but in affective paraphrenia I did. Repeatedly, I was able to confirm psychosocial theories about the genesis of schizophrenia, but in no case concerning schizophrenia as a whole. Each theory applied only to one of the different forms of schizophrenia.

The affective paraphrenics are frequently the youngest of the siblings. Among our 120 affective paraphrenics there were 36 youngest and only 17 oldest siblings. We know that the youngest children are often kept in the role of a child by their parents when they should be allured to

mature. Observations in identical twins are suggestive in this sense. In one case the maturation of both twins had been retarded because the rigorous and harsh father had suppressed the activity and affectivity of the girls. This could have applied even more to the second born twin who fell ill seven years earlier than her sister. In another case the girls were never able to live an independent life. They were not allowed to undertake any activity without asking permission from their mother. In adolescence they were not allowed to make date with a young man. An incident demonstrates the high degree to which the mother dominated her daughters. When one of them was over 30 years old and had been divorced she wanted to marry another man whom her mother did not approve of. As she attempted to resist her mother she was beaten by her. Later she fell ill with affective paraphrenia. Her identical co-twin was even more submissive and fell ill with this psychosis 22 years earlier than her sister. I did not make similar observations in other forms of schizophrenia.

Maturation is retarded to the same extent when overprotection from the mother makes independent life impossible. I observed this in an identical twin recently. The mother loved one of her children very much and always wanted to keep the girl at home. While the co-twin was with friends the index-twin was with her mother. When, in adolescence, the girl wished to go out with her sister, the mother tried to prevent this and sometimes even shed tears in grief. In contrast, the co-twin had much personal liberty and was always with friends. The different attitude of the mother toward her children had developed because the index-twin was less lively and more submissive. She fell ill with affective paraphrenia at the age of 58. The co-twin remained well until the age of 74. Then she also expressed some ideas of reference; but it was difficult to determine whether she had now become psychotic or she was only susceptible to suggestion in consequence of her old age and had accepted some of her sisters ideas. In any case, the index-twin, who was overprotected by her mother, was much more severely ill. Her maturation had been hampered.

As in this case, identical twins not infrequently have different temperaments. I particularly found this with our affective paraphrenics. In three of our seven cases the one twin was lively, the other calm. In all the three cases the twin with the calm temperament fell ill. Of the partners, apart from the co-twin just mentioned, one remained healthy, the other was much milder ill than her sister. In all cases I saw both twins and personally observed that the co-twin was much more lively. One of them was even markedly hypomanic. We may enquire whether, in the patient described overprotection and submissiveness were crucial, or, perhaps the underlying temperament alone evoked affective paraphrenia. The other two twins had not been overprotected, but were submissive to their co-twins, one of them to a high degree.

Let me now turn to the third non-systematic schizophrenia, the cataphasia, which in its excited pole corresponds to the schizophasia described by Kraepelin. Here we found that the patients relatively often originated from big cities (over 100 000 inhabitants) and relatively rarely from villages (below 2000 inhabitants). The central symp-

tom of cataphasia is represented by a disorder of thought. Thus we might suspect that the function of thinking can be damaged in big cities where there is often an excess of mental stimulation. Cognitive functions development in childhood and adolescence may be overstrained. This is a very interesting aspect which arouses the idea that in our modern time the occurrence of cataphasia must have increased, for technical development has so rapidly progressed and thinking is much more strained than in former times. Indeed, we found the incidence of cataphasia had increased. We examined our 1400 patients during the course of 15 years. We made three groups and separated patients examined in the first five years, in the second five years, in the third five years and then in each group we compared the numbers of patients suffering from the different forms of schizophrenia. The number of cataphasias had increased from group to group, relative to the other forms.

Finally, I should like to discuss manic-depressive illness and "pure" depressions. The hereditary loading of these two forms is more different than other authors have found. When differentiating according to course (monopolar versus bipolar) many manic-depressives are erroneously assigned to the pure depressions as they by chance had only gone through depressive phases, which generally are much more common. The cross-sectional picture is also different in the two conditions. We have differentiated on this basis and found 20.0% ill siblings and 18.3% ill parents with manic-depressive illness; but only 3.1% ill siblings and 5.8% ill parents with pure depressions. In the first case a dominant heritability can be assumed though external factors must contribute to the manifestation of the illness. In this psychosis the abnormal behaviour of a psychotic parent seems to be significant, for probands with psychotic parents had 28.1% ill siblings, and probands with healthy parents only 15.5%, though these "healthy" parents had the full hereditary predisposition to the illness.

Among our pure phasic psychoses the euphoric form showed still fewer ill relatives than the depressive form. The figures just mentioned (3.1% and 5.8%) include the euphoric form. After separating the two psychoses we found 4.5% ill siblings and 7.8% ill parents in the depressives, whereas in the manias there were 1.2% ill siblings and 2.1% ill parents. In the euphoric form family history is less prominent. As noted above, the existence of pure manias is still predominantly denied. The low figures demonstrate that these patients belong even less than depressives to manic-depressive illness with its high hereditary loading. So monopolar mania is an independent entity, too.

Pure manics have relatively many siblings, pure depressives relatively few. However, just as we found in two of the cycloid psychoses, this difference concerns only the older siblings, so that I again conclude that a mutual influence operates in early childhood. As siblings stimulate each other we can envisage the possibility that too much stimulation in childhood may promote the occurrence of mania, while too little stimulation may promote the occurrence of depression. If this is the case, not only siblings, but also other people (above all parents) can stimulate the child too much or, on the other hand, not enough. Seven

purely depressive probands had a depressive parent (six females and one male), one purely euphoric patient had an ill mother who was euphoric, too. Perhaps manic parents stimulate their children too much, depressive parents too little. Hereditary influences are not decisive, since nearly all of the ill parents were mothers (seven of eight parents).

The finding that manics have many siblings and that depressives have few has an important transcultural aspect. In developing countries mania is relatively common, in industrial countries depression much more frequently occurs. This difference was noted by Kraepelin after he visited psychiatric institutions in Java. There is a parallel, in developing countries families are large, in industrial countries families are small. Various causes may account for the different incidence rate of manias and depressions, but a dependence on family sizes also has to be taken into account. I do not know whether in industrial countries mania was more common in former times when families were larger. In this connection, the question may be raised whether the incidence of schizophrenia has increased in our century. My opinion is: some forms of schizophrenia have increased, others have decreased. The insidiously progressive schizophrenias, i.e., the systematic

forms, in my classification, are certainly more common at the present time. Some remitting and periodic forms occurred more frequently in former times.

A similar difference in the occurrence of schizophrenia seems to exist between industrial and developing countries as many authors have described. See Jilek (1974) and Jilek & Jilek-Aall (1970). Motility psychosis is usually assigned to the schizophrenias, and runs a markedly periodic course and probably occurs more frequently in developing countries. Since in these countries the families are larger, this fits with our finding that patients with motility psychosis have relatively many siblings.

Let me close with a general remark. You may ask why I still speak of endogenous psychoses though I presented evidence of many external influences. Why do I not add "so-called"? The external events create a disposition to psychoses in childhood and adolescence. From this time onwards, the individual has an internal propensity from which later the psychosis originates. No external influence is usually operative at the onset of this illness. In the exogenous psychoses the illness immediately follows the external influence.

The Relationship of Anxiety and Depression: A Review of the Literature

CHRISOUULA STAVRAKAKI and BEVERLEY VARGO

The nature of the relationship between anxiety and depression has been much debated. The research in the past 15 years is reviewed in the context of three conceptual models: (a) anxiety and depression differ quantitatively; (b) anxiety and depression differ qualitatively; and (c) combined anxiety and depression syndromes (anxious depressions) differ both quantitatively and qualitatively from either pure anxiety or pure depression. The major areas of research—phenomenological, treatment, course and outcome—are considered and findings in support of each position reviewed.

In recent years, there has been an increased emphasis on the phenomenology of the various disorders of mood. This has received its impetus from attempts to construct a clinically relevant taxonomy of the affective disorders by identifying operationally defined criteria to delineate one disorder from another. This is difficult because of complex symptom patterns in which there is considerable overlapping of symptomatology between two disorders. Such is the case with anxiety and depression. There are many anxious patients who present with concurrent symptoms of depression, and many depressed patients who present with concurrent symptoms of anxiety. How these patients are diagnosed has implications for both treatment and prognosis.

This paper reviews the literature on the relationship between anxiety and depression over the last 15 years. It is not an exhaustive review but an attempt to consider the major research areas for future study. An overview of the nosological problems inherent in understanding how anxiety disorders and affective disorders are related can be found in Snaith (1981).

Review of Existing Literature

Currently there are two opposing conceptual models, as well as a third intermediary position defining how anxiety and depression are related. These focus on anxiety and depression as; (a) variants of the same

disorder differing quantitatively (unitary model); (b) distinct disorders differing qualitatively (pluralistic model); and (c) a mixture of the two syndromes, phenomenologically different from either primary anxiety or primary depression (anxious depressive position). The following is a description of each position, the variables on which anxiety and depression have been compared, and the research findings on which the model is based.

Unitary Position

Clinical variables: The overlapping of clinical symptomatology between anxiety and depression has been cited as the greatest source of support for the conceptualisation of the two disorders as represented by a continuum. Gersh & Fowles (1979) conceive of them as two symptomatic stages of affective disorder with the ratio of anxiety and depressive symptoms varying over time such that the diagnosis depends upon when in the course of illness the evaluation is made. This was supported by Kendell (1974), who studied the stability of clinical diagnosis over a period of five years: comparing the diagnoses of 2,000 patients for two separate hospital admissions, there was a change in diagnosis from anxiety to depressive disorder for 24%, while for 2%, the change was in the opposite direction.

Studies of patients suffering from anxiety neurosis have found a high prevalence of depressive symptoms, severe enough to qualify for a secondary diagnosis of depression, while secondary anxiety has been found to occur in a comparable percentage of depressed patients (Fawcett & Kravitz, 1983). Estimates of depressive symptoms in anxious patients are as high as 65% (Roth *et al*, 1972): irritability, mild agoraphobia, anxiety, agitation, and ideas of guilt were common in both the anxious and depressed patients in their sample. Clancy *et al* reported that 44% of their sample of 112 anxious patients, interviewed six years after their key illness, were diagnosed as having a secondary depression in

TABLE I
Unitary position

<i>Study</i>	<i>Subject population</i>	<i>Variable(s) examined</i>	<i>Results</i>
Roth <i>et al</i> , 1972	Anxious and depressed inpatients	Clinical symptoms	65% of anxious patients had concurrent depressive symptoms
Fawcett & Kravitz, 1983	Research Diagnostic Criteria for major depression	Clinical symptoms	42% of major depressive disorder patients had moderate worry; 29% had history of panic attacks; 19% had moderate phobic symptoms
Dealy <i>et al</i> , 1981	General anxiety or panic attacks	Clinical symptoms	33% had secondary depression
Clancy <i>et al</i> , 1978	Experimental-anxiety neurotic and general medical patient control—surgical patients	Clinical symptoms	44% of anxious neurotics had secondary depression
	Secondary depression	Family history	No differences in family history for anxiety and/or depression between pure anxiety group and mixed anxiety depression group
		Course/outcome	Average of five years from onset of anxiety to development of depression
Lesse, 1982	Anxiety patients	Course/outcome	Stress—anxiety—depression axis
Kelly & Walter, 1969	3 clinical groups, 1 normal group	Personality traits	No difference in neuroticism score (Maudsley Personality Inventory) of anxious and depressed patients
Johnstone <i>et al</i> , 1980	Unselected non-psychotic outpatients with scores of 2+ on observed anxiety, depression, or both	Treatment response	Amitriptyline resulted in improvement for both anxiety and depression
		Rating scales	Ratings of anxiety and depression did not discriminate between the two groups; correlation between two sets of scales increased over time
Mendels <i>et al</i> , 1972	Female psychiatric inpatients	Rating scales	Failure to find separate anxiety depression factors, high correlation between anxiety and depression rating scales
Schapira <i>et al</i> , 1971	Anxious and depressed inpatients	Prognosis	Anxiety states of long standing tended to acquire depressive symptoms

addition to the primary diagnosis of anxiety, compared to 7% of a surgical control group. Their findings were replicated by Dealy *et al* who reported that 33% of their patients had a diagnosis of secondary depression. An association between panic attacks (anxiety neurosis) and depression has also been found: Dealy *et al* reported that 64% of their anxious patients who experienced panic attacks had secondary depression, compared to 29% without secondary depression, while analysis of the data of Fawcett & Kravitz revealed that 29% of their depressed sample had concomitant panic attacks.

Both Clancy *et al* and Dealy *et al* in their studies of anxious neurotic patients who were either diagnosed as having a secondary depression or not, found no difference between the two groups in terms

of mean age of onset, duration of illness, suicide attempts, or family history of psychiatric illness. This led them to conclude that depression and anxiety were clinical variants of the same disorder.

Treatment and treatment response: Further support for an unitary orientation comes from treatment studies in which anxious patients have responded favourably to antidepressants (Kelly *et al*, 1969; King, 1962; Sargant & Dally, 1962), and for which success has been reported with anxiolytics in depressed patients (Henry *et al*, 1970; Hollister *et al*, 1967; Overall *et al*, 1966). Johnstone *et al* (1980) found no significant drug effect which could differentiate patients on the basis of either clinical or

self-ratings of anxiety and depression: amitriptyline proved to be superior to diazepam in the treatment of both anxious and depressed patients.

Course and outcome: The concept of anxiety and depression as a continuum has been further supported by research which has hypothesised the aetiological factor of anxiety in depression. Roth *et al* (1972) reported an early age of onset for anxiety compared with depression, and noted that long-standing anxiety states tended to acquire predominant depressive characteristics with the passage of time (Schapira *et al*, 1972); Clancy *et al* found an average length of five years between the onset of anxiety and the development of secondary depression. In agreement with this position is the stress→anxiety→depression axis postulated by Lesse (1982) to explain the relationship between the two disorders. While not ruling out the possibility that in some situations, depression may be the primary response to stress, Lesse stated that he had not been able to document an acute or subacute severely depressed state in a patient who had not manifested symptoms and signs of anxiety prior to the onset of depression. Hays (1964) also reported that many depressive reactions are preceded by prodromal periods of chronic anxiety.

Rating scales: The failure to find separate factors of anxiety and depression (Mendels, 1972; Johnstone *et al*, 1980) in anxiety and depression rating scales, and the high correlation between the two sets of scales have also been cited as evidence for the quantitative model. Mendels *et al* (1972) factor-analysed the scores of six self-rating mood scales; analysis of the data for 76 female psychiatric inpatients resulted in the extraction of two factors accounting for 68% of the total variance. All of the scales, except for two of the MMPI, loaded highly on the first factor, suggesting that it constituted a dimension of general psychiatric disturbance. They concluded that in a psychiatric sample, homogeneous as to sex, self-rating scales of anxiety and depression do not separate different sets of symptoms.

This failure to find separate factors might have been dismissed as being due to the relative unreliability of self-reports of behaviour, but it was also demonstrated to be true of observer-rated scales. In their study of treatment response to anxiolytics and antidepressants, Johnstone *et al* rated their patients on the Hamilton Depression Inventory and the Hamilton Anxiety Inventory at several specified

time-intervals during the trials. For all patients, the correlation between ratings of anxiety and depression increased over time; at week one, it was +0.53, while at week five it had increased to +0.77.

Thus, the unitary position for the relationship of anxiety and depression is supported by the overlapping of symptomatology between the two syndromes, by the lack of stability of the clinical diagnosis between anxiety and depression, by the similarity of anxious patients with and without secondary depression on several variables, by the tendency for patients suffering from long-standing anxiety states to develop depressive symptoms, by the failure to find separate dimensions of anxiety and depression in both self-rated and observer-rated scales, and by the lack of a specific response to drug treatment.

Pluralistic position

The most widely published advocates of the position that anxiety and depression are separate and distinct entities have been Roth *et al* (Newcastle Group). Their studies showed a separation between clinical groups of anxious and depressed patients in terms of a number of variables—clinical symptoms, personality, treatment and treatment response, course and outcome, prognosis, and rating scales. This Group, while cognisant of the overlapping of symptomatology between depression and anxiety, suggested that with the use of appropriate statistical methods, the two disorders could be shown to differ on certain dimensions. Tentative support for their viewpoint has been achieved, using the statistical techniques of principal components analysis and discriminant function analysis (Prusoff & Klerman, 1974; Derogatis *et al*, 1972a), although others have failed to replicate their results (Mendels, 1972; Johnstone *et al*, 1980).

The Newcastle Group published a series of studies establishing the independence of anxiety and depression. A sample of 145 inpatients, diagnosed as anxious or depressed on the basis of their predominant mood state, were evaluated—at the key illness and at follow-up—in terms of clinical variables, prescribed treatment and treatment response, personality and an outcome component used to assess prognosis. Mountjoy & Roth (1982a & b) replicated the earlier research on clinical variables, and extended the analysis to rating scales, but unlike the previous sample of inpatients, this one excluded patients with endogenous depression and included daypatients and outpatients.

TABLE II
Pluralistic position

<i>Study</i>	<i>Subject population</i>	<i>Variable(s) examined</i>	<i>Results</i>
Mountjoy & Roth, 1982(b)	Anxious and depressed inpatients, outpatients, and day patients	Clinical symptoms	Principal components identified a bipolar factor; discriminant function analysis separated the two groups
Newcastle Group, 1970-72, Roth <i>et al</i> , 1972, Schapira <i>et al</i> , 1971, Kerr <i>et al</i> , 1970, 1972, Gurney <i>et al</i> , 1970, 1972	Anxious and depressed inpatients	Personality traits	Anxiety characterised by personality traits of dependence, immaturity, hysteria, neuroticism, and poor social adjustment; depressed more stable, mature and independent
		Treatment/treatment response	Anxiety states high neuroticism scores on Maudsley Personality Inventory; depression higher extroversion scores
		Course/outcome	Depressed group more frequently prescribed ECT and tricyclics; anxiety group treated with sedatives & tranquillisers; better response to ECT and tricyclics for depressed group at discharge and at six month follow-up
		Prognosis	Anxiety states had an earlier onset and a longer duration
		Family history	Poorer prognosis for anxiety states
Zitrin <i>et al</i> , 1980	Agoraphobics	Treatment response	Greater neurotic illness in families of anxious patients
Mountjoy & Roth, 1982(a)	Anxious and depressed inpatients, outpatients, and day patients	Rating scales	Negative relationship between depression in agoraphobics and response to imipramine
Prusoff & Klerman, 1974	Anxious and depressed outpatients	Rating scales	Separate anxiety and depression dimensions
Derogatis <i>et al</i> , 1972(a)	Outpatients with primary anxiety or depression	Rating scales	Discriminant function analysis of Symptom Checklist factors discriminated between anxious and depressed groups
Crowe <i>et al</i> , 1980	DSM III criteria for panic disorder	Family history	Identified depression factor in Symptom Checklist ratings of anxious and depressed groups; could not identify anxiety factor in depressed group
Van Valkenburg <i>et al</i> , 1984	Anxious neurosis and depressed patients	Family history	Morbidity risk for panic attacks but not for other anxiety disorders or depression higher in anxious neurotics
Kelly & Walter, 1969	Experimental-nonagitated depression control-normal	Response to stress	Greater family history for depression in major depressive disorder patients
			Anxious patients had mean basal forearm blood flow significantly greater than that of depressed patients

Clinical symptoms: Analysis of clinical symptoms for the anxious and depressed groups of the Newcastle studies demonstrated an earlier age of onset, greater prevalence of psychiatric disturbance in first-degree relatives, poorer social adjustment, personality traits of dependence and immaturity, and longer duration

of the illness for the anxiety states, compared with the depressive illness (Roth *et al*, 1972).

Personality characteristics: Personality differences between the groups on the Maudsley Personality

Inventory (Kerr *et al.*, 1970) related to higher neuroticism scores and lower extraversion scores for anxiety states, compared to depressive states, both at key illness and at follow-up; it was concluded that the extraversion dimension represents a more stable aspect of personality, while neuroticism is primarily a measure of anxiety. These results were not replicated by Kelly & Walters (1969), who found no difference between their anxious and depressed patients in terms of the neuroticism score on the Maudsley Personality Inventory.

Treatment and treatment response: The anxious and depressed groups of the Newcastle studies also differed both in the prescribed treatment and in their response to two of four treatment strategies. Both ECT and tricyclic antidepressants were significantly more beneficial for the depressed group, in contrast to the anxious group; 24 out of the 28 depressed patients improved with ECT, compared with two out of the nine anxious patients; 23 out of the 27 depressed patients benefited from treatment with tricyclic antidepressants, whereas only five out of the 18 in the anxious group showed improvement.

Prognosis: The differentiation between anxiety states and depressive illnesses made on clinical grounds was upheld by differences in prognosis (Schapira *et al.*, 1972): there was a consistent tendency for the whole range of symptoms studied at follow-up to be more frequent and more severe in the anxious group of patients. A principal components analysis, carried out on 53 items used in the assessment of mental state at follow-up, showed a better prognosis for depressive patients in terms of global adjustment.

Rating scales: Mountjoy & Roth (1982a) factor-analysed the scores from both observer-rated (Hamilton Scales for Anxiety and Depression, Newcastle Anxiety Depression Scale) and patient-rated scales (Zung Depression Scale, a scale for anxiety, phobic scales for agoraphobia and for school phobia). All of the scales loaded positively on the first component, which accounted for 44% of the variance; it was interpreted as a general factor of severity, and there was no significant difference between the diagnostic groups in their mean scores on this component. The second component was bipolar, and a subsequent discriminant function analysis separated the two clinical groups at a statistically significant level, resulting in a miss-classification rate of 32%.

Prusoff & Klerman (1974) analysed the Symptom Checklist, a 58-item self-report inventory. Their sample consisted of 364 anxious outpatients and of 364 depressed patients, matched with the anxious group for race, sex, age, and social class. Previous factor analysis of the Symptom Checklist had identified five separate factors: the patients' scores on these factors were analysed by discriminant function analysis. The depression and somaticism factors contributed to the discrimination between the groups, while the anxiety factor failed to make a significant contribution to the discrimination. Similar results were reported by Derogatis *et al.* (1972a), who examined the factorial invariance for the same scale. A factor analysis of the scores of 641 anxious neurotic outpatients and 251 neurotic depressed patients identified a depression factor in both groups, but the anxiety factor was only identified in the anxious group. It was concluded that the different pattern of factor loadings of the two groups on the depression dimension were evidence for differences between anxious and depressive syndromes.

Family history: Several investigators have cited differences in terms of family history between the two disorders as supportive of the pluralistic model. Roth *et al.* found a greater prevalence of neurotic illness and personality disorder in first-degree relatives of anxious patients, whereas van Valkenburg *et al.* (1984) found a greater family history for depression in patients diagnosed as primary affective disorder. Crowe *et al.* (1980), in a sample of patients with anxiety neurosis (panic attacks), reported a higher morbidity risk in first-degree relatives for panic disorder but not for other anxiety disorders or for depression.

Physiological: There is physiological evidence in support of the separate entity hypothesis (Kelly & Walter, 1969): when subjected to experimentally induced stress, anxious patients had a mean basal forearm blood flow significantly greater than that of depressed patients. Mountjoy & Roth (1982b) also found a tendency for anxiety states to show increased physiological response, while depressive states were frequently associated with psychological response to stress.

In summary, the differentiation of anxiety states from depressive states in adults has been made on the basis of clinical items, rating scales, prognosis, personality, treatment response, course and outcome, physiological response to stress, and family history data.

TABLE III
Anxious depression position

Study	Subject population	Variable(s) examined	Results
Van Valkenburg, <i>et al.</i> , 1984	1) Primary anxiety (panic attacks) 2) Primary depression 3) 2 mixed groups of anxiety and depressive syndromes	Clinical symptoms Treatment response Course/outcome Family history	In general, differences between the "pure" and "mixed" groups were found on the variables under examination "Mixed" groups showed increased agitation, hypochondriasis, depersonalisation, derealisation, chronic depression Increased proportion of "mixed" group failed to improve when given spectrum of pharmacological and psychosocial intervention "Mixed" groups more likely to have poor psychosocial outcome; more chronic course "Mixed" groups did not differ significantly in family history of depressive or anxiety disorders
Clancy <i>et al.</i> , 1978	Anxious patients with and without secondary depression	Course/outcome	Anxious neurotics with secondary depression have a more severe and chronic illness
Schapiro <i>et al.</i> , 1971	Anxious and depressed inpatients	Prognosis	Anxiety symptoms in depressed patients and depressive symptoms in anxious patients indicated poorer prognosis
Paykel, 1971	Depressed inpatients, out-patients, day patients, emergency patients	Rating scales	Factor analysis delineated a subgroup of depression characterised by anxiety and tension

Anxious-depressive position

In addition to anxiety and depressive disorders, a group of patients has been identified with coexistent anxiety and depression; while seeming to support the unitary position, this group show phenomenological differences from either generalised anxiety disorder or major depressive disorder. Overall *et al.* (1966) factor-analysed the Brief Psychiatric Rating Scale scores of a sample of male inpatients; this divided the sample into three sub-groups, with one (anxious-tense) characterised by anxiety, tension, and depression. Similarly, Paykel (1971) identified by cluster analysis a group suffering from both anxiety and depression.

Downing & Rickels (1974) compared target symptomatology, illness history, and prognosis for a sample of patients with a mixed anxiety-depression diagnosis assigned to treatment with either anti-depressant or anxiolytic drugs. They concluded that

the group with mixed symptomatology demonstrated differences in terms of clinician and patient ratings of anxiety, depression, and treatment response; and that the diagnosis of mixed anxiety depression was not representative of a homogeneous group.

Van Valkenburg *et al.* (1984) examined the validity of the anxious-depressive syndrome in a sample of 114 patients who met the diagnostic criteria for anxiety neurosis (DSM-III panic disorder) and/or for depression. This differed from the study by Downing & Rickels (1974) in the use of panic attack as a clinical marker for anxiety syndromes and in the use of operationally defined criteria to delineate their groups, thereby greatly enhancing the homogeneity of the diagnostic groupings. The assessment of the groups was on several variables—clinical symptoms, course and outcome of the illness, and family history. In terms of clinical symptoms, the groups in which there was a mixture of anxiety and depression showed a marked similarity, with observed

differences attributed to severity; both groups had a similar family history of psychiatric illness.¹ In contrast, significant differences between the groups of anxious depressives and those with primary anxiety or primary depressive disorder were reported for treatment response, psycho-social adjustment, and prognosis. The finding that functioning is most impaired in those patients in whom anxiety and depression co-exist corroborated earlier research. Clancy *et al* compared anxious neurotics with and without secondary depression: their anxious-neurotic group who subsequently developed secondary depression had a more serious course and outcome, leading to the conclusion that anxious patients who develop a secondary depression have a more severe and chronic anxiety illness, which predisposes them to depression.

In summary, research indicates that when the two syndromes coexist, there is increased chronicity of the illness, reduced response to conventional therapies, and a poorer prognosis. Anxiety and depression in combination appear to represent both a quantitatively and qualitatively separate syndrome, unlike either anxiety disorder or affective disorder in many important respects.

Critical analysis of previous research

There are many sources of discrepancy in the studies examining the relationship between anxiety and depression. These range in scope and severity from the relatively minor inconsistencies in scoring procedures to major issues concerning semantic, methodological and interpretative differences. These discrepancies could, directly or indirectly, give rise to the observed results, thereby helping to explain some of the apparently contradictory findings.

Semantic inconsistencies: The largest stumbling block to the study of the relationship of anxiety and depression has been one of semantics, and relates to the multiplicity of the concepts of both anxiety and depression. Semantic inconsistencies between the various studies arise from two sources—discrepant use of the terms by investigators, and a lack of differentiation between the terms by patients in reporting on their symptoms. The introduction of operationally defined criteria for delineating the disorders has alleviated some of these difficulties, but confusion over the use of the two terms is still common among both clinicians and patients. 'Psychotic/endogenous' and 'neurotic/reactive' depressions are vague and ill-defined: they can either represent the two ends of a continuum, thus differing quantitatively, or two separate entities, differing qualitatively. In addition, the complaint of anxiety

can denote a normal response variance, a trait, or a state, and has been used interchangeably with depression.

Methodological differences: The next largest source of variance between the studies has been methodological differences in sample populations, sources of data, range of symptomatology assessed, and level of analysis.

Sample selection: The procedures for selecting subjects have varied from preselection by clinical diagnosis to recruitment through radio advertising (Dealy *et al*, 1981) so that patients one investigator may exclude are the subjects for another study. Different exclusion and inclusion criteria have resulted in varied demographic as well as clinical patient characteristics of the samples—differences in terms of degree of psychopathology, sex, and socio-economic level. Studies included only outpatients, only inpatients, or a combination of both. Based on the assumption that inpatients are 'sicker' than outpatients or day patients, a study composed only of outpatients may not find the same association between anxiety and depression as one composed of inpatients. There is a similar lack of generalisability for samples homogeneous as to sex: three studies (Prusoff & Klerman, 1974; Mendels *et al*, 1972; Zitrin *et al*, 1980) included only female subjects, while in three others (Downing & Rickels, 1974; Derogatis *et al*, 1972a; Dealy *et al*, 1981), there were more women than men. Since data indicate that females report symptoms of anxiety and depression in greater numbers than males, results obtained in all female samples can only apply to other samples of females.

Samples have also differed in socio-economic level: both Prusoff & Klerman (1974) and Derogatis *et al* (1972a) excluded patients from the lowest social class because earlier research had indicated that the factor structure of a lower-status anxious group is qualitatively distinct from that of the other social classes. To what extent the results from research which has included lower class subjects are distorted is not presently known.

There are also inconsistencies in the homogeneity of the samples: sometimes heterogeneous groups have been intentionally selected (Mendels *et al*, 1972), while other samples have varied in their degree of homogeneity from the absence of diagnostic groupings (Johnstone *et al*, 1980) to the use of a clinical marker for delineating groups (Van Valkenburg *et al*, 1984). The success of the various selection procedures in achieving homogeneity

depends to a great extent on the degree to which empirically defined criteria are used in the selection and diagnosis of the clinical groups. However, even this is not enough to assure comparable samples, since the claim that diagnoses were made according to DSM-III criteria is not sufficient to establish that these criteria were used as intended or as others have used them (Helzer & Coryell, 1983). In addition, many of the clinical diagnoses of the present studies were made prior to the advent of operationally defined diagnostic criteria.

Procedural differences: Procedural differences between studies also help to account for some inconsistent results. Differences in focus, in the nature and source of the data, and how the data are analysed vary across studies:

- (i) Focus: The focus of studies on the relationship of anxiety and depression has ranged from discriminating anxiety from depression (Newcastle studies) to examining the etiological role of anxiety in depression (Clancy *et al*, 1978), to an assessment of clinical, family, and outcome variables in anxious-depressive states (Van Valkenburg, 1984).
- (ii) Sources of data: Studies differ in the source of their data and in the degree of reliability inherent in those sources; in those reviewed, the source of information includes clinical interviews, observer-rated scales, patient-rated scales, physiological measures, and retrospective recall. Many have used clinical interviews for diagnosis, for obtaining clinical histories, or for rating the presence and severity of psychopathology. The interviews have varied in their degree of structure, whether the interviewer is the same person or a different one from the clinician who made the original diagnosis, whether the interviewer is 'blind' to the diagnosis, and to the number of raters present: all of these factors have a bearing on the reliability of the data obtained.

Observer-rated scales have generally been found to be a more reliable source of information about severity of psychopathology than self-reports of behaviour, which are subject to distortion either through the respondent 'faking bad' in a bid for attention or 'faking good' to appear mentally healthy. Denial of symptoms, especially in the acute phase of illness, has been cited as one of the major reasons for the low concordance between clinician and patient ratings (Prusoff *et al*, 1972). There is a similarly low concordance between patient and clinician ratings for bipolar depression (Donnelly *et al*, 1980). It becomes clear that the reliability of self-reports depends both on the type of depression

(unipolar/bipolar) and on the stage in the illness at which the patient is assessed. Self-reports of behaviour also presuppose that the patient has the ability to analyse and make accurate judgement on his internal states, but this varies considerably from patient to patient, depending on such factors as intellect, verbal ability, and severity of the disorder. Clinician-rated scales give a more accurate picture of the disorder for several reasons. Firstly, they have the advantage of a far greater variety of behaviour on which to make judgements, e.g. facial expression, degree of tearfulness, amount of agitation or retardation, and body language. Secondly, the clinician has considerably more knowledge of the whole range of psychopathology, and thus a larger perspective on which to base his judgement.

The reliability of data in studies which have used retrospective recall of childhood events (Roth *et al*, 1972) or required the patient to reconstruct the course of an illness (Shapira *et al*, 1972) is questionable, as these reports are subject to errors of memory. Without substantiating evidence, they are generally an unsatisfactory source of information.

Range of psychopathology assessed: The selection of clinical items is also variable across studies, as is the choice of rating scales. Clinical items and rating scales which assess a wide range of symptoms have greater chance of finding significant differences between groups than fewer items which assess a narrower range of symptoms. Derogatis *et al* (1972a) cite the small number of items relating to anxiety on the Symptom Checklist as a plausible explanation for the failure to find a dimensional construct of anxiety in their sample of depressed neurotics.

Timing of disorder in relation to course of the disorder: Studies have also varied in the timing of the study: in some, the focus is on the current mental state while in others, it involves a follow-up assessment. Since the symptoms of anxiety and depression vary during the course of the disorder, different results could be a function of the length of time after the initial illness until the follow-up assessment.

Statistical analysis: There are also wide variations in the use of statistical techniques to analyse the data; these vary from univariate frequency counts, t-tests, and analysis of variance, to the sophisticated multivariate techniques of multiple regression, factor analysis, and discriminant function analysis. Many of the statistical tests have certain assumptions such as normality of the distribution and homogeneity of variance, which must be met if the results are to be

valid. Frequently, insufficient information is provided to assess whether these important assumptions have been met or not.

One misuse of statistical methods in several of the studies is evaluation of the differences in means between groups by multiple t-tests. When these are computed on the same data, the range of scores increases at a faster rate than the standard deviation, so that non-significant results will be erroneously reported as significant.

Level of interpretation: The level of interpretation is also variable between studies, with some examining the relationship of anxiety and depression at the symptom level (Dealy *et al*; Clancy *et al*), while others examine differences at the level of factors (Newcastle studies; Prusoff & Klerman; Mendels *et al*; Derogatis *et al*, 1972a). Discussion at one interpretational level is not necessarily comparable with discussion at a different level.

There has also been some selectivity in what individuals choose to interpret as being significant: in the factor analysis of rating scales by Mountjoy & Roth (1982a), their first component accounted for 44% of the variance; all the scales loaded substantially on this component, and it was described as a general dimension of severity of psychiatric disturbance. This is basically the same result that Mendels *et al* obtained when they factor-analysed self-rated scales, but whereas Mendels *et al* chose to interpret this as evidence for the fact that anxiety and depression are variants of the same disorder, Roth & Mountjoy go on to interpret the second component, and use it in a discriminant function analysis to demonstrate that anxiety and depression are separate entities. Thus, we have similar results interpreted very differently.

These semantic, methodological, and interpretational disparities between studies evaluating the relationship of anxiety and depression make it difficult to compare the results of one with another. Indeed, inconsistencies inherent in the various research designs may explain why one investigator gets one set of results while another, doing a similar procedure, gets the opposite set of results. The need for replication of the crucial studies is obvious, if the ambiguity in the present findings is to be resolved.

Discussion

Anxiety and depression are classified as separate disorders—clinically through DMS-III and statistically through discriminant function analysis. However, certain issues such as the presence of mixed anxiety/depression patients, the relatively high miss-classification rate (which casts some doubt as to the feasibility of being able to discriminate between anxiety and depression in clinical practice), and contradictory research findings suggest that there is no unequivocal solution to the problem of how anxiety and depression are related. Several issues are in need of clarification and resolution, including replication of research findings, cross-validation of discriminant function coefficients, assessments of biochemical markers as a means of separating the two groups, relationships within the sub-categories of each major disorder (e.g. endogenous depression and generalised anxiety disorder), and the relationship between anxiety and depression in children. Based on the assumption that childhood and adult psychopathology are continuous, an examination of the nature of this in children might help to clarify the relationship in adults.

A Follow-Up and Family Study of Briquet's Syndrome

S. B. GUZE, C. R. CLONINGER, R. L. MARTIN and P. J. CLAYTON

For many years we and other colleagues in the Department of Psychiatry at Washington University School of Medicine in St Louis, Missouri have been concerned with the need to develop widely accepted, valid diagnostic criteria for psychiatric disorders. The aim has been to identify patient groups as homogeneous as possible. Diagnostic criteria, such as those used in this study, were therefore developed with the goal of maximising specificity (i.e. reducing false positives) while keeping sensitivity as high as possible (i.e. keeping false negatives low).

This paper deals with some issues concerning Briquet's syndrome (hysteria, somatisation disorder): in particular, the validity of specific diagnostic criteria (measured by consistency of diagnosis over time) and the pattern of illness seen in first-degree relatives of index cases. This report is part of an extensive investigation of patients attending the Washington University Psychiatry Clinic in St Louis, carried out under 'blind' conditions. Different individuals studied the patients at index and at follow-up and examined the patients' first-degree relatives. The follow-up and family studies were performed without any knowledge of the findings concerning any individual in the other component, or of the findings concerning any individual at index.

The overall investigation was designed to evaluate and improve diagnostic criteria for a variety of psychiatric disorders by studying the longitudinal course and by identifying patterns of illness in close relatives of index cases. The study resulted from an initial intention to repeat and refine a series of previous investigations concerning Briquet's syndrome by selecting a new population of patients. It quickly became apparent that in order to obtain a group of patients with Briquet's syndrome it would be necessary to screen many other patients, and it was decided that the study should be enlarged to include patients with a wide variety of psychiatric disorders.

Method

Selection of subjects

The selection of the 500 index patients has been described elsewhere. The selection process was designed to identify a representative cross-section of patients attending the Washington University Psychiatry Clinic. The patients were examined initially during a period of 28 months, from July 1, 1967 to November 1, 1969. Data from this phase of the study have already been presented (Guze, Clayton & Woodruff, 1975; Guze, Woodruff & Clayton, 1971*a,b,c*, 1972, 1974; Liskow *et al.* 1977; Woodruff, Clayton, Cloninger & Guze, 1976; Woodruff, Clayton & Guze, 1969, 1971, 1972, 1975, 1976; Woodruff, Guze & Clayton 1971*a,b*, 1972*a,b*, 1973, 1974; Woodruff, Guze, Clayton & Carr, 1973).

Between 1969 and 1973, 1249 interviews with first-degree relatives of the index subjects were carried out. We had intended to interview an average of three first-degree relatives for each index case. It became apparent, however, that progressively more time and effort were required to locate and interview relatives as the number of completed relative interviews grew. It was decided to stop before the full 1500 interviews had been completed, because we concluded that it would require another two years to interview the additional 250 relatives.

The follow-up interviews were carried out from 1973 to 1979. This resulted in a 6-12 year follow-up for individual patients. Of the 500 index patients, 6 were unavailable for follow-up because they could not be located, 41 were known to be dead, 31 refused to be interviewed or were repeatedly uncooperative, and 422 were interviewed.

Research interviews

The same standardised, structured interview was used in all three phases of the study: index, family, and follow-up (Guze, 1976). In each phase the interviews were carried out by different individuals, who were blind to information concerning individual patients obtained in the other phases.

Diagnoses

The general approach to psychiatric diagnosis has been described previously (Guze, 1976). The specific criteria used in this study (Martin *et al.* 1985) were very similar to those of Feighner *et al.* (1972).

The interviews with the relatives were conducted, after appropriate training, by psychiatry residents and fourth

*Papers presented at the Quarterly Meeting of the Royal College of Psychiatrists, London, November 1984

year medical students; the latter were selected from those with a strong interest in psychiatry who had already completed their psychiatry clerkships. The protocols were reviewed by Robert A. Woodruff and two of the authors. The protocols from the follow-up interviews (conducted by CRC and RLM) were reviewed by PJC and SBG. Following each protocol review, diagnoses were made according to the specified criteria, and appropriate forms were completed for coding and keypunching.

In view of the large number of patients (500), relatives (1249), and total interviews (nearly 2200), and the long interval involved in the overall study (14 years, as protocol review continued until 1981), it is highly unlikely that the protocol reviewers were any less blind than were the individual interviewers.

At follow-up a second review of each case was carried out a few weeks or months after the initial protocol review, in order to consider additional information obtained from physicians, clinics, and hospitals visited by the index patients, and from other informants in those cases where a follow-up interview had not been feasible. A second follow-up diagnosis was then made for each case. This was based on all available information except for the index interview and the relative interviews. These second follow-up diagnoses were used for the analyses in this paper. Comparisons between the follow-up interview information and that obtained from records and other informants will be presented in future publications for the entire range of psychiatric diagnoses.

Previous work

The present investigation of Briquet's syndrome follows a number of earlier studies (Arkonac & Guze, 1963; Bibb &

Guze, 1972; Cloninger & Guze, 1970*a,b*, 1975; Cloninger *et al*, 1975, in press; Farley *et al*, 1968; Gattfield & Guze, 1962; Guze, 1963, 1964, 1966, 1967, 1970*a,b*, 1975, 1983; Guze & Purley, 1963; Guze, Woodruff & Clayton, 1971*b*, 1972; Liskow *et al*, 1977; Martin *et al*, 1979; Perley & Guze, 1962; Woerner & Guze, 1968; Woodruff, Clayton & Guze, 1969, 1971). This previous work suggests that the diagnostic criteria used selected patients (nearly all of whom were women) whose clinical course and familial illness patterns provided strong evidence for the validity of the diagnosis. These patients show a consistent clinical picture over time, with very few turning out to have other disorders that might, in retrospect, account for the original clinical picture. (This is in striking contrast to the findings when patients are selected primarily on the basis of conversion symptoms). The same disorder occurs with considerably increased frequency among first-degree female relatives, while antisocial personality is encountered at increased frequency among first-degree male relatives and spouses. Furthermore, Briquet's syndrome and antisocial personality are encountered together in the same individual much more frequently than would be expected by chance. This personal and familial aggregation of the two disorders has led to the hypothesis that Briquet's syndrome and antisocial personality result from similar combinations of aetiological factors and that the clinical manifestations of these underlying aetiological factors depend largely on the sex of the individual: women are more likely to show the pattern of Briquet's syndrome, while men are more likely to show the pattern of antisocial personality.

Results

Table I shows the follow-up diagnoses given to those

TABLE I
Follow-up diagnoses of Briquet's syndrome according to index diagnoses

patients with index diagnoses of Briquet's syndrome; Table II shows the index diagnoses that had been given to those patients with follow-up diagnoses of Briquet's syndrome. At both index and follow-up, a number of patients did not meet the criteria for either definite or probable Briquet's syndrome; nor did they meet the criteria for any other diagnosis. Since their symptoms resemble Briquet's syndrome more than anything else, they were designated as 'undiagnosed, ? Briquet's syndrome'.

About two-thirds of the patients who received the diagnosis of definite or probable Briquet's syndrome at index received the same diagnosis at follow-up (Table I). Another 14% of such index cases were considered to be undiagnosed, ? Briquet's syndrome at follow-up, so that nearly four-fifths of index Briquet's syndrome patients continued at follow-up to present with either the same diagnostic picture or one resembling it enough for them to be suspected of suffering from the same condition. On the other hand, over 20% of these index patients received other diagnoses at follow-up. A similar pattern was seen in those patients receiving a diagnosis of undiagnosed, ? Briquet's syndrome at index.

The data indicate that more patients received diagnoses of Briquet's syndrome or of undiagnosed, ? Briquet's syndrome at follow-up than at index, and that the retrospective consistency was much less than the prospective consistency (Table II). Only one-third of patients with follow-up diagnoses of Briquet's syndrome had received the same diagnosis at index, and only 12% of patients considered undiagnosed, ? Briquet's syndrome at follow-

up had received the diagnosis of Briquet's syndrome at index. In total, only about half of the patients with follow-up diagnoses of Briquet's syndrome had had the diagnosis made or suspected at index; the comparable figure for the follow-up cases considered to be undiagnosed, ? Briquet's syndrome was about one-quarter. Whether prospectively or retrospectively, primary affective disorder and primary anxiety neurosis were the most frequent diagnoses made in the inconsistent cases.

Tables III and IV present the diagnoses in first-degree relatives according to the proband diagnoses. In Table III the probands are characterised in terms of the follow-up diagnoses; in Table IV, in terms of either index or follow-up diagnoses. The latter analysis was carried out because of the inconsistency observed in the proband diagnoses over time. The results are very similar. They indicate that the diagnostic criteria for Briquet's syndrome select a group of patients whose first-degree female relatives show a severalfold increase in the frequency of the same syndrome, as well as in the frequency of antisocial personality, and whose first-degree male relatives also show a significantly increased frequency of antisocial personality. It should be noted here that the probands who had never received any diagnosis suggesting Briquet's syndrome included many with antisocial personality. It would be reasonable to assume that their first-degree relatives include many with the same disorder, so that the frequency of this condition in the overall sample of relatives is probably especially elevated, tending therefore to obscure the full significance of the elevated prevalence of antisocial personality among

the relatives of probands with Briquet's syndrome. Our strategy for breaking the blind diagnostic codes prevents us from opening up the data concerning the relatives of probands with antisocial personality until we are ready to study the probands directly.

No cases of Briquet's syndrome and only three cases of undiagnosed, ? Briquet's syndrome were found in male relatives. No increased frequency of either Briquet's syndrome or antisocial personality was found among the relatives of probands considered undiagnosed, ? Briquet's syndrome. No familial association was seen between Briquet's syndrome in the probands and either schizophrenia, primary affective disorder, alcoholism, or anxiety neurosis in the relatives

Discussion

Several features of this study deserve emphasis. The overall research design emphasised 'blindness' to a degree seldom achieved in such clinical investigations. The index subjects represented a broad cross-section of psychopathology, so that a wide range of diagnoses had to be considered in evaluating the follow-up data and the study of relatives, thus

adding to the diagnostic difficulty. All of the interviews were carried out by clinically trained individuals. The same interview protocol and explicit diagnostic criteria were used in all phases of the investigation, and these are related conceptually and historically to widely used instruments and diagnostic systems (Feighner *et al*, 1972; Guze, 1976; Robins *et al*, 1981; Stoltzman *et al*, 1981). The results of the overall project attest to the value of careful follow-up and family studies in improving diagnostic validity (Robins & Guze, 1970).

Overall, the results confirm previous work concerning follow-up and familial illness patterns associated with Briquet's syndrome. Briquet's syndrome runs in families. There is no familial association with schizophrenia, primary affective disorder, primary anxiety neurosis, or alcoholism in the absence of antisocial personality. The association with antisocial personality is especially noteworthy, because the diagnostic criteria in the two conditions are independent and without overlap. Furthermore, as noted previously (Cloninger & Guze, 1970a,b; Guze *et al*, 1971a,b; Cloninger *et al*, in press, Guze,

1976), the repeated observation that Briquet's syndrome is seen predominantly in women while antisocial personality is encountered predominantly in men emphasises the importance of the association confirmed in this report, indicating that the two disorders must share important aetiological factors.

The diagnostic inconsistency observed is compatible with our clinical experience in treating patients with Briquet's syndrome. Many patients, especially early in the course of our contact with them, prove to be inconsistent historians. This was demonstrated in a previous follow-up study in which a major source of diagnostic inconsistency was attributable to inconsistent reporting of symptoms (Martin *et al*, 1979). It is often not until we have followed individual patients for some time that the full clinical picture becomes evident. We have learned that this pattern is itself a characteristic of the disorder. It accounts in part for the confusing clinical course, the overtreatment, and the therapeutic frustrations encountered in the care of these patients. Experience with such patients underscores our conviction that

it is very important to talk to relatives and friends and to seek information from other physicians, hospitals, and clinics whenever faced by any difficult or puzzling case. In fact, in the previous follow-up study diagnostic consistency was appreciably improved when independent medical records were considered as well as interview data.

Our data suggest that once a diagnosis of Briquet's syndrome is made, however, a reasonable diagnostic consistency may be expected (about 80% in this sample), but that other psychiatric diagnoses will be made or seriously considered in patients who ultimately meet the criteria for Briquet's syndrome, but who fail to meet them initially (about half the cases in this sample).

The failure to find any characteristic familial illness pattern associated with probands considered undiagnosed, ? Briquet's syndrome but who had never received a definite or probable diagnosis requires comment in view of the fact that an overlap over time between this diagnosis and the diagnosis of Briquet's syndrome was seen. The data suggest

that the proper explanation is simply one of relative probability. Individuals considered undiagnosed, ? Briquet's syndrome at any one time include some who are really cases of Briquet's syndrome, which will become evident on another occasion, while others are suffering from other disorders which will also be evident on other occasions, but which sometimes resemble Briquet's syndrome. In any particular sample, the relative proportions of the two groups will determine whether or not a familial association with Briquet's syndrome will be found. In this study, after a 6–12 year follow-up, the failure to present with the full Briquet's syndrome indicates that they were false positive cases. Our findings confirm our clinical experience that careful follow-up of uncertain cases of Briquet's syndrome will usually clarify the diagnosis. If, however, the clinical picture remains uncertain, our family data indicate that such patients should not be classified with Briquet's syndrome.

Summary

The study began with the systematic clinical evaluation of a cross-section of 500 of the clinic's patients. This was followed by a 'blind' follow-up of the index subjects and a 'blind' study of first-degree relatives. The present report deals with the diagnosis of Briquet's syndrome (hysteria, somatisation disorder) at index, at follow-up, and among first-degree relatives. The data indicate that the criteria used for the diagnosis of Briquet's syndrome select patients who show a high degree of diagnostic consistency over many years, although not all patients who meet these criteria at follow-up receive the diagnosis of Briquet's syndrome initially. Most importantly, the diagnostic criteria select cases associated with a strong familial increase in the risk of Briquet's syndrome and in the risk of antisocial personality. Both are increased among first-degree female relatives, while only antisocial personality is increased among first-degree male relatives.

The Importance of Hysteria

H. MERSKEY

Hysteria has been a topic of interest throughout the history of medicine; those who have been concerned with it include Galen, Paré, Sydenham, Charcot and

Freud. Anyone who chooses to proclaim its importance, therefore, might be asked to provide some reason for gilding the lily. Controversies have

always attended the subject, and different disciplines still disagree over it. The diagnosis, which occurs in the International Classification of Diseases (ICD-9, 1978) has been deprecated on both sides of the Atlantic (Slater, 1965; DSM-III, 1980) and also advocated with varying degrees of fervour (Walshe, 1965; Lewis, 1975; Merskey, 1979). It is a subject of historical study (Veith, 1965; Walker, 1981; Shorter, 1984); there have been at least nine monographs on it since 1977 (Horowitz, 1977; Krohn, 1978; Jakubik, 1979; Merskey, 1979; Roy, 1982; Riley & Roy, 1982; Colligan *et al*, 1982; Weintraub, 1983; Ford, 1983), and there is a steady flow of paper on the topic of hysteria or its major subdivisions (eg, hysterical personality, conversion symptoms) or pseudonyms and partial pseudonyms (eg, somatisation disorders, borderline personality, and operant pain).

Furthermore, the whole field of chronic pain is a prominent theme in which at least some aspects of hysteria require consideration (Merskey, 1980). Nevertheless, it is probably true that the volume of publications on hysteria is less than on other topics, in relation to its supposed importance.

For convenience of definition, I shall follow the ICD-9 classification of hysterical neurosis (300.1) and hysterical personality (300.5). For the subtypes of hysteria, I have suggested the following (Merskey, 1979):

- (a) hysteria with one or two symptoms, usually motor or dissociative (as in amnesia), sometimes pain
- (b) polysymptomatic hysteria, especially hypochondriasis and Briquet's syndrome as described by Guze and his colleagues (the St Louis group) and now elaborated in DSM-III under the heading of somatisation disorder
- (c) hysterical elaboration of organic complaints
- (d) symptoms of self-induced illness or self-damage in abnormal personalities ranging from anorexia nervosa to hospital addiction
- (e) psychotic or pseudopsychotic disorders (Ganser's syndrome, hysterical psychosis)
- (f) hysterical personality
- (g) culturally sanctioned endemic or epidemic hysteria.

Since different aspects of this list will occur in many different situations, we have a hint that the theme might be an important one both in medicine and in society. I will start by considering the epidemiology of somatic complaints not due to physical illness and probably not due to psychophysiological causes.

Frequency

If we look only for the florid symptom picture described by the St Louis group, we find that 1–2% of parous women (Farley *et al*, 1968) or women under investigation in a medical ward (Woodruff, 1968) present this pattern of illness. There are similar findings in other surveys (Majerus *et al*, 1960; Murphy *et al*, 1962). About 10% of psychiatric in-patients in university hospitals (Bibb & Guze, 1972) and 5–11% of psychiatric out-patients (Farley *et al*, 1968) are similarly affected. Folks *et al* (1984) found, in 1000 consecutive psychiatric consultations in a general hospital, that the prevalence of conversion disorder was about 5%; one third of these cases had somatisation disorder. Katon *et al* (1984) have reviewed the prevalence of somatisation in primary care and have shown that it is at least relevant, in the majority of general practice cases, whether the patients are seeking treatment for minor somatic complaints because of major psychological problems, or whether it is of psychophysiological origin rather than the result of a conversion process. Many of these symptoms may also be related to depression, but it is impossible to read their survey, or to consider this field in any depth, without reaching the conclusion that an understanding of psychological mechanisms in the production of bodily complaints is fundamental to an understanding of medical practice as a whole.

Chronic pain has a frequency of 11% in a fairly typical population (Crook *et al*, 1984). When it is a subject for treatment in pain clinics there is always a group in whom anxiety and hysterical mechanisms are believed to play an important role (Merskey, 1980). Ford (1983) provides evidence from various sources to show that physical complaints on the basis of psychological illness (somatisation) affect 50–60% of medical clinic patients; 27% of patients with symptoms had no evidence of disease (Garfield *et al*, 1976). Spear (1967) found that 66% of psychiatric in-patients and day patients had pain. If the complaints are hysterical, even in a minority of these patients, this is a matter for concern in clinical practice.

Diagnostic problems

Hysteria keeps recurring as an issue in difficult diagnostic cases. Whenever we are at the margin of our ability to decide on a diagnosis, hysteria is a diagnostic possibility. If a somatic symptom has a psychological cause, and if benign physical methods of investigation are not enough to rule out organic disease, the patient may be heavily and even dangerously over-investigated. Alternatively, a lack of

adequate technology and a proper unwillingness to undertake hazardous investigations for obscure symptoms may encourage a false attribution of psychological symptoms to a physical illness.

I have emphasised the frequency of somatic symptoms of psychological origin. At the same time, we have to recognise the existence of a group of symptoms for which advances in clinical knowledge have enabled an organic diagnosis where formerly the label 'hysteria' was applied; if such cases are not correctly diagnosed the psychiatrist will be expected to cure a physical disorder with antidepressant drugs or by psychotherapy.

I should like to offer some examples of this dilemma. Firstly, there is a form of paroxysmal hemicrania which is now a well-defined syndrome (Sjaastad & Dale, 1974), but which was earlier diagnosed as headache of psychological origin. Secondly, the thoracic outlet syndrome, particularly if it is relatively mild and accompanied only by modest changes, has often been called 'neurotic'; recently I have seen six such patients whose symptoms were precipitated by a flexion-extension ('whiplash') injury of the cervical region, in whom physiotherapy had failed to provide relief and in whom first rib resection was a satisfactory procedure.

Globus hystericus provides a third example. Sydenham (1697), following earlier writers, spoke of "suffocation of the Womb in which the Belly and Entrails rise upwards towards the Throat". Purcell spoke of the symptom of difficulty in swallowing as if "a hard ball pressed against the outside of their throats; sometimes as if it were a Stick thrust down their Throats...". Traditionally, the symptom was regarded as hysterical. However, it is plausible that anxious patients may swallow air or have trouble with anorexic sensations and have difficulty in swallowing. A disorder of the oesophagus, thought to be a spastic phenomenon, was in fact demonstrated by Jacobson (1924) in an early radiological investigation. Malcolmson (1966, 1968) showed, in a series of 307 patients, that only 21% were completely normal on physical and radiological examination; 30% had a physical lesion (eg, cervical spine osteophytes, overactive cricopharyngeus, hyperplastic tonsils, goitre, postcricoid web or enlarged lymph nodes) which explained the symptom, and 49% had a gastrointestinal disturbance below the pharynx, for example hiatus hernia or duodenal ulcer. More evidence in the same direction has been produced by Delahunty & Ardran (1970), Hunt *et al* (1970), Watson & Sullivan (1974), and Lehtinen & Puhakka (1976). There may still be some patients with globus, now best termed globus pharyngis (Malcolmson,

1966, 1968), whose symptoms are psychological in origin either on the basis of anxiety or a conversion mechanism. However, most cases have a physical basis.

Facial dyskinesias and torticollis provide a fourth example. The diagnosis of psychological disorder has to a considerable extent been superseded by an organic diagnosis. I first learned to think of these as more likely to be of organic rather than psychological origin through the influence of my late colleague Dr R. T. C. Pratt. He observed that neurologists seemed to have more difficulty in making up their minds about organic or psychological causes in relation to torticollis and abnormal movements than on any other topic, and also that the symptoms tended not to respond so well to the usual treatments for anxiety or hysteria compared with other more recognisable somatic anxiety or hysterical symptoms. On one occasion, in 1969, with the knowledge of all participants we showed a patient with abnormal facial movements to six neurologists; three said her symptoms were psychological, and three said that they were physical in origin. All six gave impressive arguments to back up their opinions, but the one whose views seemed to me to be most cogent was Dr M. J. McArdle, who observed a retrocollis and abnormal movements of the soft palate. Since that time neurologists have more readily diagnosed facial dyskinesias as organic, for two reasons: firstly, they may be provoked in Parkinsonism by levodopa, and secondly, phenothiazine drugs used in the treatment of schizophrenia may produce such movements.

A fifth condition which I have seen diagnosed as hysterical, but know to be organic, is that of painful legs and moving toes (Spillane *et al*, 1971). Nathan (1978) has now shown that this is a characteristic syndrome with a specific organic basis in damage of either the dorsal nerve roots or the spinal cord.

The final example is the whiplash syndrome. It is well established that people who undergo rear-end collisions in motor vehicles typically show a pattern of development of cervical pain, headache and muscle tenderness. Animal experimentation has shown that there are recognisable and distinct soft tissue lesions, some of them severe, like retro-oesophageal haematoma, which can even be demonstrated in accident victims if the patient complains of difficulty in swallowing and an X-ray is taken at the right time (McNab, 1973). Evidence (Merskey, 1984) supports an organic aetiology in most of these cases. Moreover, patients who have had such injuries may not recover merely because litigation issues are settled (Mendelson, 1982; Merskey, 1984). What used to be called hysterical or compensation

neurosis is now better considered to be a symptom based on physical disability. It may carry in its wake some secondary depression and secondary psychological manifestations, but when a condition is poorly understood and the patient is referred from one medical department to another, it is understandable that psychological symptoms should develop; these will include anger, frustration, irritability, and some criticism of the medical profession. In such conditions hysteria should not be diagnosed in the absence of positive grounds for the diagnosis.

Social consequences

The figures quoted above for the frequency of somatic symptoms in medical practice give some indication of the importance of the production of bodily symptoms. The numerous social implications of 'illness behavior' or 'abnormal illness behavior' (Pilowsky & Spence, 1975) cannot be considered here in detail. Some of the many cases of attempted suicide, some disability claims and financial settlements, and perhaps many changes in family relationships will be influenced by hysterical symptoms. In military practice, particularly when the danger is great and the opportunity for a 'respectable' hysterical illness exists, the numbers increase considerably. By April 1918, according to Hurst (1940), there were over 20 000 cases of 'war neurosis', who received invalid pensions. It is not known what proportion of these patients suffered from hysteria and what proportion from anxiety states or depression, but the frequency of hysteria in that era is well attested to by the numerous books and other publications on the topic of 'shell shock' and 'war neurosis' (Merskey, 1979). Since the First World War such cases have been less frequent; during the Second World War the organisation of the Allied military psychiatric services was such that the development of hysterical symptoms was discouraged. However, hysterical manifestations have always been found in men under stress. Likewise, epidemics of hysteria occur, most often in girls' schools (Sirois, 1974).

It has been suggested that one of the important theoretical consequences of the recognition of combat neurosis and hysteria in the First World War was the strength it gave to the argument that, since so many men who often seemed otherwise normal were affected, hysterical symptoms were not necessarily sexual in origin.

Symptoms from thoughts

The single most important aspect of hysteria is its contribution to our understanding of the mind. To

place this in context it is worthwhile considering the 17th century concept of hysteria, about which I have written in more detail elsewhere (Merskey, 1983). Sydenham (1697) included two major ideas under the rubric of hysteria. Firstly, he indicated that emotional stress disturbs the function of the nervous system; even before the time of Galen others had recognised an influence of the mind upon the body (Veith, 1965, and Hunter & McAlpine, 1963, give several illustrations from writers such as Bartholomeus Anglicus, Elyot, Langton and Paré).

Secondly, Sydenham provided a catalogue of bodily changes presumed to result from this disturbance. Some of these are clearly organic: apoplexy with hemiplegia, epilepsy, vomiting bile, and swollen legs, for example; others, such as excessive laughter, tears and labile emotions, reflect general emotional disturbance, or more specifically hysteria. Some, such as diarrhoea, may be psychosomatic in the strict sense of being related to peripheral somatic changes induced by psychological causes. Sydenham did not elucidate these matters. The critical point is that hysteria was considered to be a mixture of symptoms that we would now call organic, psychosomatic or perhaps hysterical; at the time, they were all thought to result from emotional causes. Gradually, the organic symptoms have been clarified (as the examples given earlier indicate), but it was still not really possible for the distinction between a hysterical symptom representing an idea and a physiological symptom presenting an autonomic disturbance to be made before the days of modern physiology and anatomy. Only with Sir Benjamin Brodie (1837) did some of these possibilities begin to emerge, although precursors existed. These were reviewed by Wright (1980), who remarked upon the fact that Descartes explained strange aversions by past experience. For instance, a cat might have jumped into a baby's cradle, thus causing a dislike of cats without the adult retaining any memory of it afterwards. Descartes also discovered that he was attracted to cross-eyed women, and attributed this to his love, as a young child, for a girl who looked after him and who had this defect. It is noteworthy that the recollection and analysis of the memory cured him of that particular fixation. We see here some recognition that thoughts might cause symptoms, although the symptoms which are caused are also psychological ones.

Others saw physical symptoms being transmitted by example. Robert Boyle is cited by Wright as noting that it is common for one hysterical woman, when she observes another in a fit, to be "infected with the like strange discomposure" and Blackmore (1725) wrote: "Terrible ideas, formed only in the

imagination, will affect the brain and the body with painful sensations. . .". These authors recognised the way in which ideas could produce physical symptoms, but until the age of modern neurology and neurophysiology it was probably impossible for a consistent distinction to be established in respect of the topic, except perhaps for epidemic hysterical complaints, which were well reviewed by Hecker (1844).

The new conception really began with Sir John Russell Reynolds, who was Professor of Medicine at University College Hospital. At a meeting of the British Medical Association Reynolds described "three cases of paralysis dependent upon idea". The report was published the same year (Reynolds, 1869) and seems to have been the first systematic discussion of the theme. Certainly Charcot (1889), who said that the idea was long known, gave Reynolds full credit for his comments. Charcot was then inspired to produce symptoms in patients by the implantation of an idea under hypnosis, and this constituted the second step in the recognition of the special characteristics of the hysterical symptom. The third step we owe to Freud (Breuer & Freud, 1893-5) and his explanation of the origin of the symptom in conflict or in repression. This is so well known that I will not dwell upon it; nor upon the fact that it was the foundation of psychoanalysis, although I also take that to be an important contribution of hysteria to mankind.

The significance of hysteria and its interest lie above all in this reflection of the way in which the mind may transform a person's concept of himself or a part of his body. It has become an avenue to the discussion of personality types, a theme for evaluation in social relationships, a key to motives, and a highway to the unconscious. It is difficult to ask more of a single condition.

The demand on the doctor

However, this condition (whether single or multiple) gives us yet another theme to tackle, and one which is personally demanding for all doctors. Hysteria imposes a test on our professional skills. We can, if we wish, dismiss it as counterfeiting, none of our business, and something with which physicians need not be concerned once they have established the true situation. For reasons which deserve longer discussion elsewhere, I think that this would be an inappropriate professional response. The physician should be as committed to understanding and treating patients with hysteria as those with any other psychological or physical disorder. In order to provide that understanding and treatment, he needs an extensive background in traditional organic medicine and, equally, a tolerant and flexible approach based on psychiatric skills. That combination offers a challenge to the personal qualities of every doctor who aims to treat patients.

Epilepsy and Hysteria

G. W. FENTON

Charcot's term ‘hysteroepilepsy’ implies brain hysteria. No such direct link between these two mechanisms in common between epilepsy and conditions exists. Nevertheless, there are a number of

indirect associations between epilepsy and hysteria that can lead to confusion in the differential diagnosis and management of the patient with seizures.

Hysterical pseudoseizures are attacks of sudden unconsciousness, usually (but not invariably) associated with dramatic motor manifestations, which simulate epileptic attacks to a varying degree. The term 'pseudoseizure' is not ideal, since it conveys the impression that the event is not really a seizure. The term 'pseudoepileptic seizure' is more appropriate, since it acknowledges the occurrence of seizures and their resemblance to genuine epileptic fits, but avoids the implication of physiological mechanisms in common between epilepsy and hysteria.

The other terms used to describe hysterical fits ('simulated epilepsy' and 'psychogenic seizures') should not be used. 'Simulated epilepsy' implies malingering; this is rarely the case, since the patient with hysterical fits is not aware of the underlying psychological motivation for them. Psychological stress is important in precipitating frank epileptic attacks in some epileptic patients. Indeed, a recent survey of unselected primary care patients suffering from epilepsy reported that 72% of the sample of 300 found emotional upset to be accompanied by an exacerbation in seizure frequency (Dowds *et al.*, 1983). Hence the term 'psychogenic seizure' should be avoided.

Pseudoepileptic seizures are not an infrequent manifestation of hysteria, being the second most common form found in 381 patients with hysteria (Ljungberg, 1967); 20% of this series presented with hysterical fits. More recently, Reed (1975) found a 9% prevalence among patients at the Maudsley Hospital admitted between 1949 and 1964 with a diagnosis of hysteria. Rather more surprising is the paradoxical observation that genuine epilepsy and pseudoepilepsy can coexist in the same patient. A present or past history of epilepsy is found in a significant number of patients with pseudoepileptic seizures referred to hospital for investigation, the prevalence varying from 12% to around 65% (Merskey, 1978a; Fenton, 1982; Lesser, 1985). Doubtless the wide variance reflects the heterogeneous nature of the series of small groups of patients reported in the literature from different centres.

It may seem strange for people with genuine fits to display pseudoepileptic attacks as an hysterical manifestation. One would think that genuine epileptic fits would provide a more than adequate locus for the illness-rewarding behaviour of the patient who responds to stress using hysterical mechanisms. However, the real epileptic attacks of the patient

with pseudoepileptic seizures are often well-controlled by anticonvulsant therapy. Indeed, there is evidence that the development of classical hysterical fits can be facilitated by anticonvulsant drug toxicity (Niedermeyer *et al.*, 1970), but this would only account for pseudoepileptic seizures in a minority of patients with epilepsy. Previous episodes of unconsciousness, either experienced personally or observed within the family or work environment, often provide a model for the choice of pseudoepileptic seizures as the hysterical manifestation. Roy (1980) found a personal history of epilepsy or an experience of working in a medical environment in about one-third of a series of patients with hysteria, the majority of whom had hysterical convulsions. Therefore, if the person with epilepsy is predisposed to hysterical mechanisms as a means of coping with a stressful situation, the previous experience of genuine epileptic attacks will have a major influence in determining the selection of fits as the hysterical manifestation.

Pseudoepileptic seizure patients also display many other features indicative of psychopathology: a family history of psychiatric illness, a past personal history of psychiatric disorder with suicidal attempts, a diagnosis of personality disorder, sexual maladjustment, disturbed interpersonal relationships with parents or heterosexual partner, an unsatisfactory current life situation, and concurrent affective symptoms. They also tend to have significantly higher scores on the General Health Questionnaire, the Wakefield Self Assessment Depression Inventory and the Hamilton Rating Scale for Depression (Roy, 1977; Lesser, 1985).

Epileptic and pseudoepileptic seizures: differential diagnosis

Clinical manifestations

In the differential diagnosis between epileptic and pseudoepileptic seizures, the clinician should always supplement the patient's account of the seizures by obtaining an accurate history from a reliable observer and be thoroughly familiar with the clinical features and the classification of the wide variety of epileptic seizure phenomena and their pathophysiological mechanisms (Commission on Classification, 1981).

Typical of the pseudoepileptic grand mal attack is the marked involvement of truncal musculature, with some opisthotonos (a complete *arc de cercle* is now very rare) and random struggling or thrashing movements of the limbs, trunk or head. Side-to-side throwing or rolling of the head or body is common.

The pseudoconvulsive movements may increase if restraint is imposed, and the patient may struggle to free himself from the restraint and even become combative; this is in marked contrast to the stereotyped tonic-clonic convulsions of the grand mal epileptic fit.

Cyanosis, an invariable feature of grand mal convulsions, is rare in pseudo-grand mal attacks, although it may occur as a result of breath-holding. The pupillary reaction to light and the corneal reflexes are retained during a pseudoepileptic seizure, but may be difficult to elicit due to the patient actively moving about or to upward deviation of the eyes. Indeed, during the pseudoepileptic attack the patient may actively resist attempts to open his eyes. Pressure on the supraorbital notch may cause head withdrawal, indicating that the patient has some perception of pain. Responsiveness to painful stimuli is entirely lost during the tonic-clonic phase of an epileptic grand mal attack. The facial expression during a grand mal seizure is characterised by trismus in the tonic phase and symmetrical twitching during the clonic phase. In the pseudo-grand mal fit, the face reflects either repose or a variety of emotions, including ecstasy.

The level of consciousness may fluctuate during the pseudoconvulsive phase, so that the patient may be able to recall some or all of the events of the fit. However, the presence or absence of diminished awareness during the attack can be difficult to determine; moreover, some epileptic attacks of partial origin can occur in clear consciousness. Nevertheless, the demonstration of retained awareness of the environment while bilateral or whole body convulsive movements are in progress is strongly in favour of the diagnosis of a pseudoepileptic seizure. A marked emotional display either after, or (on rare occasions) during an attack, with the patient in floods of tears or shouting obscenities, is again suggestive of an hysterical fit.

Following a genuine grand mal attack, the plantar responses become extensor for a short time. However, the responses must be elicited carefully, since it has been shown that healthy adults can learn to dorsiflex their toes in response to plantar stimulation of the foot (Lesser, 1985). If the tongue is bitten at all in pseudoepileptic fits the lacerations tend to be minor, involving the tip rather than the side of the tongue, or the lips rather than cheeks. Loss of bladder control and injury by falling during pseudoepileptic attacks may occur, but are uncommon.

The epileptic aura signals the transition of the episodic interictal firing of epileptogenic tissue into the continuous discharge that recruits additional neuronal circuits and provokes the clinical manifes-

tations of the fit as it spreads to involve large areas of brain. Unless the patient has multifocal disease, which occurs only in cases of extensive brain damage, the aura of the epileptic patients, if present at all, will be identical or very similar during different attacks. Neither the presence nor absence of an aura, nor the type of the aura, provides useful differential diagnostic information.

Subjective phenomena herald the onset in a significant minority of pseudoepileptic fits. Specific symptoms include palpitations, malaise, choking, dizziness, paraesthesiae in the face or extremities, pain, olfactory and gustatory hallucinations, and visual illusions and hallucinations (Lesser, 1985). Pain, either in the body, extremities, or head, is rare as an epileptic aura. The only exception is a focal seizure of parietal origin, in which there is usually contralateral paraesthesia with spread of a seizure activity to the motor cortex so that the affected extremity will show clonic convulsive movements. On the other hand, a prodromal complaint of headache is quite common in pseudoepileptic seizures (Finlayson & Lucas, 1979). Auras that contain a great number of somatic or visual symptoms which vary on different occasions suggest pseudoepilepsy.

Epileptic attacks usually begin abruptly. Although many pseudoepileptic fits do so also, a consistently gradual onset favours the latter diagnosis. Precipitation by shock, surprise or emotional distress must be interpreted with caution, since such factors may trigger epileptic attacks in susceptible individuals. Pseudoepileptic seizures may be provoked by hyperventilation, which will on occasion precipitate a true ictal event. The seizure duration is the same for the two types of attack, though a gradual termination is more often observed in pseudoepilepsy (Lesser, 1985).

Pseudoepileptic attacks usually occur when other people are present, especially those of significance in the patient's life, but there are exceptions. Unlike true epileptic seizures, pseudoepileptic seizures never occur during sleep. Careful enquiry about the person's state of awareness at the time of the onset of the seizure is necessary, since patients may develop pseudoepileptic attacks immediately on waking from sleep. Pseudoepileptic seizures are sometimes frequent, attacks recurring many times per day; this is unusual in real epilepsy, with the exceptions of status epilepticus, petit mal absences and some patients with minor complex partial seizures. Indeed, the recurrence of persistent and frequent major fits despite adequate anticonvulsant drug dosage, evidence of satisfactory compliance, and serum concentrations within the optimal range should raise the suspicion of pseudoepileptic seizures.

Classification of pseudoepileptic seizure manifestations

Analysis of videotaped pseudoepileptic fits has led to attempts to classify the range of clinical phenomena. In a study of 27 patients (Gulick *et al*, 1982), motor manifestations were found to be bilateral in 15 and unilateral in 3, while 8 displayed multiple behavioural phenomena and 3 decreased responsiveness only. Luther *et al* (1982) observed generalised convulsive-type attacks in 15 out of 37 attacks in 30 patients; 21 resembled elementary partial seizures with secondary generalisation, and one a complex partial seizure.

Lesser (1985) has proposed the following main categories of manifestation: sustained or repetitive muscular contractions, either unilateral or bilateral; muscle inactivity or loss of tone; unresponsiveness alone; and unresponsiveness in association with quasi-purposeful or automatic behaviours. Episodes may occur either with or without an aura and, in any one patient, more than one of these patterns may coexist.

Some unusual presentations of pseudoepilepsy

Repeated pseudoconvulsive seizures without recovery of consciousness between attacks, with incontinence of urine or tongue biting during some of the fits, may simulate status epilepticus, leading to transfer to an intensive care unit and exposure to the potential hazards of apnoea and hypotension due to the vigorous pharmacological treatment of the apparent status. Toone & Roberts (1979) described three such patients, and made the point that some patients with pseudoepileptic seizures have attacks that bear a striking resemblance to genuine epilepsy. This is particularly true of patients with some experience or knowledge of epilepsy, a problem among nurses with pseudoepileptic seizures; two of the patients described by Toone & Roberts were nurses. I vividly recall a trained psychiatric nurse who had a series of hospital admissions for control of status epilepticus. It was only when the hemiconvulsions suddenly and inexplicably changed from one side of the body to the other after the intravenous cannula and drip set delivering the medication and nutritional fluids had been inserted in the opposite arm that the suspicion of pseudoepilepsy was aroused! This diagnosis was confirmed during a prolonged period of in-patient observation, including gradual withdrawal of anticonvulsants and replacements by a placebo. In organic status epilepticus the patient does not regain consciousness in the postictal period, and has further seizures separated by intervals of not more than 15–30 min.

As the status progresses the seizures become shorter and less vigorous, but there are never any thrashing or throwing movements. The diagnosis should be verified by electroencephalography (EEG); there will always be seizure discharges in association with the attacks in status epilepticus. In pseudostatus epilepticus the EEG tracing shows only muscle movement and electrode artefacts during the pseudoconvulsive episodes.

On rare occasions focal neurological signs can be manifest during pseudoepileptic fits. One patient has been described who produced pupillary dilation and an extensor plantar response by pressing his thumb into the left side of his neck (Hammond, 1948). Another rare but potentially confusing manifestation of pseudoepilepsy can be recurrent injury. I recall a young student nurse with pseudoconvulsive seizures; after each attack she invariably had bruising over the face, limbs and trunk. Such extensive bruising is rarely seen after a grand mal convulsion. Hence, if the nature and extent of the injuries received during a fit are inappropriate for the circumstances of the seizure, the epileptic nature of the attacks should be open to critical re-examination.

Although the most common type of pseudoepileptic seizure is the pseudoconvulsive type, less dramatic forms do occur. Some patients may present with transient episodes of unconsciousness associated with pallor and slumping to the ground without convulsive movements resembling syncope. However, in the latter condition the patient is usually responsive by the time he or she falls to the ground, the face is pale, and there is no resistance to eyelid opening or to testing the corneal reflexes. In the pseudoepileptic seizure patient the period of unresponsiveness will usually be longer, and active resistance to eye opening may be manifest. The facial colour is either normal or flushed.

Some brief attacks of pseudoepilepsy may resemble simple partial seizures of the motor type, with twitching of one side of the face or jerking of limbs down one side of the body. The cortical motor representation of the face, thumb and hand occupies the largest proportion of the lateral surface of the motor cortex (Penfield & Jasper, 1954); the trunk has a small representation, and the leg areas are on the mesial surface. For this reason, epileptic attacks originating in the motor area affect mainly the face, thumb and hand. Jerking of shoulder or elbow in the absence of jerking of face and hand is therefore unlikely to be of epileptic origin. Since in most right-handed people and in 60% of left-handed people speech is dependent on the function of the left hemisphere, a right-sided motor seizure is usually associated with speech arrest; if speech is

preserved during a clinically right-sided seizure and the patient is not left-handed, an epileptic basis is therefore unlikely. The movements of the focal motor attack are either tonic or clonic in nature, in contrast with the trembling or grossly irregular shaking of the pseudoepileptic variety. Sensory manifestations may occur as part of a minor pseudoepileptic attack. However, the location and spread of the sensory phenomena do not usually fit into a consistent and orderly pattern that reflects progressive involvement of adjacent areas of the brain by the spreading seizure discharge.

Hysterical fugue states, complex partial seizures and transient global amnesia

An hysterical fugue may be misdiagnosed as a complex partial seizure with automatic behaviour. However, automatic behaviour of epileptic origin is of brief duration, lasting minutes rather than hours. A classical temporal lobe aura may precede the attack. During an epileptic automatism there is usually evidence of clouding of consciousness, poor appreciation of the environment, and purposeless, inappropriate automatic behaviour. The duration of the hysterical fugue is hours or days. The patient's behaviour is usually well structured and co-ordinated and not inappropriate to the circumstances of the environment, despite the lack of knowledge of personal identity. Indeed, the behaviour seems goal-directed, the unconscious motivation being to escape from an intolerable situation.

Transient global amnesia is another disorder that can be confused with both hysterical fugue states and epileptic automatism. It differs from the latter condition in that the patient continues with routine activities but fails to lay down any permanent memory traces throughout the episode. Knowledge of personal identity is retained during the attack. The behaviour is well-structured and consistent with what is going on in the environment at the time. Memory gaps are not restricted to matters of personal concern nor specific emotionally loaded themes, and there are no inconsistencies in memory performance.

Other episodic organic disorders that simulate hysteria

The discussion of differential diagnosis has so far emphasised the need to avoid the mistake of diagnosing true epilepsy, when the attacks are actually those of pseudoepilepsy. Less frequent, but just as important, is the risk of wrongly attributing the

diagnosis of pseudoepilepsy to episodic disturbances of behaviour that have a truly epileptic basis.

Patients with paroxysmal choreo-athetosis suffer from episodes initiated abruptly by restless movements of upper and lower limbs which progress to typical choreiform activity. The movements may be unilateral with generalisation, symmetrically bilateral or strictly unilateral. The patients remain conscious, usually do not fall, and are acutely embarrassed by the occurrence of such attacks, which may last between half an hour and several hours. They tend to be precipitated by emotional stress, coffee, or beer, and may be aggravated by anticonvulsant medication—especially phenytoin, which is sometimes prescribed when a seizure disorder has been mistakenly diagnosed. There is frequently a positive family history for this condition.

In startle or movement-induced seizures the patients suddenly drop to the ground with associated loss of consciousness as a result of a sudden startle stimulus or of suddenly rising from the sitting position. The attack is short-lived, and the patient returns to consciousness immediately. It usually results from a myoclonic jerk, and the EEG frequently shows spike wave discharge. Myoclonic jerks occur mainly in patients with primary generalised tonic-clonic seizures, but can be a manifestation of such progressive brain syndromes as Lafora's disease, subacute sclerosing panencephalitis and Creutzfeldt-Jakob's disease. Sometimes (in primary generalised epilepsy and Lafora's disease) the myoclonus is severe and causes gross uncoordination of movement and gait. In some patients, emotional stress greatly aggravates the myoclonus. The link between the patient's emotional state, the jerking and apparent ataxia can lead to an erroneous diagnosis of hysteria, especially as the disorder may have an episodic quality and may lead to the avoidance of situations. Myoclonus tends to be worse in the mornings. The jerks often come in rapid succession, and herald a tonic-clonic seizure. EEGs frequently reveal that they are associated with bursts of generalised spike wave activity, and photic stimulation may elicit the myoclonus and associated generalised spike wave complexes.

The psychic auras that often initiate the complex partial seizures of temporal lobe epilepsy can be a bewildering and distressing experience for some patients. Those people whose habitual way of coping with psychic pain is denial may dissociate into a fugue state in response to the distressing subjective experience of the aura. Alternatively, they may respond by manifesting disinhibited, explosive behaviour in an attempt to escape the stressful

event. In my experience such reactions are rare, but undoubtedly do occur, especially in patients of low intelligence and those predisposed to using hysterical mechanisms to deal with stress. For instance, a 30 year old man of low intelligence and limited social and verbal skills had problems in relating to the opposite sex; at a time when he was having difficulties with a girlfriend, he experienced several attacks of panic followed by disinhibited behaviour. The attacks responded to chlordiazepoxide, and were considered to be an hysterical response to stress. It was only when the same sequence of events was repeated several years later, when he was having difficulties with another girlfriend, that the attacks were shown to be of temporal lobe origin with secondary fugue states.

Aetiology of hysterical pseudoepileptic seizures

Kendell (1974) and Smith (1978) have formulated essentially similar aetiological models for hysteria, in which hysteria develops as a response to emotional stress or conflict when a series of environmental, biological and personal predisposing (vulnerability) factors are present within the individual or as part of the current life situation. These are an illness-rewarding situation (when the advantages of being sick outweigh those of health), and individual variables such as female gender, youth, inferior social status, immigrant status, low intelligence, hysterical or passive-dependent-immature personality, suggestibility, difficulty in the overt expression of feelings, a tendency to dissociate and use denial mechanisms as a means of coping with stress, and personal experience of physical illness in relatives, self, peers or acquired as a member of one of the health care professions. The symptoms and signs of the resulting hysterical syndrome mimic organic disease, and permit the patient to adopt the sick role with consequent relief from the precipitating stress or conflict.

One important element missing from this model is organic brain disease. This seems to facilitate the use of hysterical mechanisms (Slater, 1965; Whitlock, 1967; Merskey & Buhrich, 1975; Merskey, 1978*a, b*; Roy, 1980, 1982) and is reported in 40–63% of patients with hysteria. Although Slater made the important observation that hysteria can herald the onset of the central nervous system disease, pre-existing organic brain disease is also a common predisposing factor to the development of hysterical symptoms.

This modified model clarifies the genesis of hysterical pseudoepileptic seizures. Precipitating stress factors are frequently present (80% of those studied

by Standage & Fenton (1975)–53% psychological and 27% physical). An illness-rewarding situation is often apparent. Anxiety and depressive mood change is common, as is other evidence of psychological maladjustment (Roy, 1977, 1980, 1982). The sex distribution is predominantly female, personality disorder is not infrequent, and organic brain disease is reported in between one-quarter and one-half of patients. The brain dysfunction tends to be acquired early in life, usually before the age of 15, and is often accompanied by cognitive impairment (Standage, 1975; Standage & Fenton, 1975; Roy, 1977). Side-effects of anticonvulsant drugs can be another factor. Previous episodes of unconsciousness, including epileptic fits either experienced personally or observed within the family or work environment, often provide a model for the choice of pseudoepileptic seizures as the hysterical manifestation. Unconscious symbolic processes are not important in symptom choice (Standage & Fenton, 1975).

Investigation

As already explained, the correct diagnosis of patients with pseudoepileptic seizures can be difficult, especially those who present with a history of both well-controlled epilepsy and frequent pseudoepileptic seizures. Many such patients will have been treated with large doses of anticonvulsant medication in the mistaken view that uncontrolled epilepsy is the problem. Even when the differential diagnosis seems straightforward, it is often impossible on an out-patient basis to elicit any underlying psychological difficulties to account for the pathogenesis of the attacks. The use of denial mechanisms in response to conflict or stress inevitably leads to defensiveness and denial of emotional difficulties during initial diagnostic interviews. Indeed, even the mere suggestion of an emotional basis for the attacks will often be angrily rejected. Similar attitudes are usually present in the patient's close relatives. To overcome these difficulties it is best to admit the patient to hospital, where the clinical pattern of the seizures can be carefully observed and described, preferably by staff who have special experience in the observation of fits.

Electroencephalography

EEG abnormalities are not infrequently recorded, but must be interpreted with caution. The presence of EEG paroxysmal abnormalities of the type associated with epilepsy does not necessarily confirm that the observed attacks have an epileptic basis. The

former can occur in the pseudoepileptic patient for one or more of the following reasons:

- (a) underlying epilepsy, usually well controlled
- (b) bursts of generalised spike wave complexes or paroxysmal theta activity, due to anticonvulsant drug withdrawal. Such withdrawal effects may persist for as long as 21 days after the end of the withdrawal phase
- (c) generalised fast spike and wave complexes are found in nearly 3% of apparently healthy people, presumably being a reflection of an unduly low convulsive threshold (Fenton, 1974).

Background activity abnormalities such as focal slow waves, a marked alpha or beta rhythm asymmetry or diffuse slowing of the dominant activity frequency are evidence of organic brain dysfunction. However, their presence in a patient with seizures of uncertain origin cannot be regarded as unequivocal evidence that the attacks are epileptic, since organic brain disease is an important predisposing factor in the genesis of pseudoepileptic seizures. Anticonvulsant drug intoxication produces diffuse EEG background dominant activity frequency slowing, and can also cause pseudoepilepsy to develop. Hence, the routine EEG is of limited help and may even be misleading in the investigation of pseudoepileptic attacks.

Prolonged EEG recording over hours or days, using either conventional leads, a videotape telemetry system, or ambulatory monitoring with a portable tape recorder that can be carried about by the patient, often makes it possible to record an actual seizure (Oxley *et al*, 1981; King *et al*, 1982). Muscle and movement artifacts caused by the convulsive movements may make the presence of ictal discharge during the seizure difficult to identify. However, scrutiny of the recording just prior to seizure onset and after cessation of the clinical seizure can be fruitful. An epileptic seizure of partial (focal) origin may be accompanied by an EEG seizure discharge lateralised to the hemisphere origin prior to onset of the clinical manifestations of the attack. In addition, during the postictal phase there may be an asymmetry of EEG background activity, with apparent reduction in normal rhythms and the appearance of slow waves over the hemisphere of origin of the seizure discharge. After a generalised convulsion there are always postictal EEG changes; transient electrical silence is followed by the appearance of irregular slow waves which, over the next few hours, are gradually replaced by normal activity. Hence, if the recording of an actual seizure is neither possible nor convenient, it is still useful to record an EEG within an hour of the occurrence of the seizure, so

that the postictal changes (if any) can be studied. However, their absence cannot exclude epilepsy, since the changes even after a real grand mal attack may be only present for a few minutes. An attack with major convulsive movements without EEG changes is almost certainly non-epileptic in nature, but in true partial epileptic seizures there may also be an absence of any scalp EEG change.

If the patient is receiving anticonvulsant therapy on admission, the medication should be continued until there has been sufficient time to observe the nature of the attacks. If the evidence in favour of an epileptic basis is not convincing, the anticonvulsant drugs can then be gradually replaced by placebos. As well as depressing cognitive function, heavy anticonvulsant medication can suppress the EEG paroxysmal abnormalities associated with epilepsy. However, it is often difficult to obtain appropriate placebo tablets. If so, the reasons for the proposed drug withdrawal will have to be discussed with the patient and the drug withdrawal procedure can then be carried out with the patient's knowledge and consent. In the event of placebos being used, the placebo nature of the medication will have to be disclosed to the patient; this is best done at an appropriate time during the parallel programme of psychotherapy. If, following withdrawal, real epileptic attacks recur, anticonvulsant medication will have to be reintroduced. The dosage required is usually small.

Other useful investigations

Serum prolactin levels rise sharply after many, but not all, generalised tonic-clonic convulsions to 1000–2000 mUnits/litre; this may be helpful in differentiating epileptic grand mal seizures from non-epileptic pseudo-grand mal attacks (Trimble, 1978; Lesser, 1985). A major difficulty is that both false-negative and false-positive results have been reported after major convulsive attacks. Furthermore, significant elevations are less common and less consistent following complex partial seizures, and do not occur after simple partial seizures (Dana-Haeri *et al*, 1983; Lesser, 1985). Therefore, postictal serum prolactin changes must be interpreted cautiously in the light of the associated clinical and EEG manifestations. Since organic brain disease is a common finding in patients with pseudoepileptic seizures as well as epilepsy, neurological investigation is not as helpful as one might predict. However, a computerised tomography scan will often identify underlying pathology of the central nervous system, and is useful in excluding progressive brain lesions that present with hysterical manifestations.

Treatment

The psychological management of the patient should run in parallel with the programme of observation and investigation. Rapport will be gradually established during the initial interviews. As rapport and mutual trust between doctor and patient develops, the façade of denial will gradually be penetrated and a process of clarification and non-directive discussion of the patient's symptoms and current life problems and their inter-relationship can begin. As the link between the fits and their emotional state begins to be understood by the patient, the acceptance of the psychogenic origin of the attacks becomes possible without loss of face. If a videotape recording of the pseudoepileptic attack is obtained, it can be used to show the patient what he looked like during a seizure. The non-epileptic nature of the movements or behaviour can be pointed out, along with a demonstration of the normal EEG data to both patient and family. This procedure can facilitate the development of insight into the nature of the seizures (Feldman *et al*, 1982).

Providing the patient's intelligence level is appropriate, and motivation for self-examination adequate, the exploratory psychotherapy can progress to an examination of the psychological meaning of the illness and the habitual defence mechanisms used against anxiety. The patients should be encouraged to acknowledge and discuss their emotional difficulties and tensions as a healthy alternative to denying their existence. Such a psychotherapeutic approach will tend to focus on an examination of the relationship between the therapist and patient (transference) and how this reflects relationships in his or her formative years and current life situation. The number of sessions of such focal psychotherapy will depend on the amount of available time and the therapist's assessment of the patient's capacity to benefit. A minimum of ten and a maximum of thirty one-hour sessions will be required. If this psychodynamic approach is inappropriate because of low intelligence, poor motivation for self-examination, or inability to cope with the inevitable transference problems, a more supportive psychotherapeutic role is still helpful, the aim being to permit abreaction, reduce emotional tension, and provide encouragement, support and guidance in dealing with current life problems.

One of the basic principles of learning theory is that patterns of behaviour that are rewarded tend to increase in frequency. When the pseudoepileptic nature of the attacks is firmly established, the staff should be encouraged to ignore their occurrence, but to respond to the patients when they are free

from seizures. The patient should be encouraged by all members of staff to express and discuss emotions when distressed. Events in the ward environment that upset the patient and are followed by attacks can be discussed and used as examples of the operation of dissociation and denial mechanisms. More healthy ways of coping with such potentially stressful events can be encouraged and rehearsed. It is important that all members of the therapeutic team adopt a consistent approach to the patient. This must be sympathetic but firm. Clear guidelines about how to handle the varied repertoire of behaviour must be formulated so that the patient is not given the opportunity to manipulate individual staff members.

As patients' awareness of their emotional difficulties grows during the psychotherapy, the fits tend to subside. However, the patients may react by becoming depressed or by developing other conversion symptoms; alternatively, they may show their distress by self-damage, damage to property, or by various types of demanding histrionic behaviour. Such behaviour should be ignored as much as possible, but if it becomes seriously disruptive firm boundaries defining the limits to be tolerated by the staff should be drawn up and communicated to the patient by the therapist. A consistent approach is facilitated when all members of staff can meet regularly to discuss management, either during regular staff meetings, ward rounds, or clinical conferences.

Work with the patient's parents or spouse is always required. Simple explanation about the nature of the attacks and their relationship to emotional conflict and tension is essential. Advice to avoid rewarding their occurrence with too much attention, sympathy or concern is necessary; again, the need for a consistent approach should be stressed. Family or marital psychotherapy may be necessary if problems exist. A further strategy of management should be based on an attempt to minimise the disadvantages of health and the advantages of sickness. This will require careful and detailed inquiry to elucidate the full implications for the patient of both states. If the stress which caused the patient to adopt the sick role is a temporary one, little is needed beyond a firm prediction of recovery and the provision of a treatment setting in which this can take place gracefully. If the advantages of the sick role are substantial and enduring, however, a carefully planned regime will be needed. This will involve the patient's relatives.

After discharge from hospital, a long-term supportive relationship with the therapist is helpful. Contact should be relatively frequent (once every few weeks) for the first few months, in order to cope with crises that may arise, followed by a gradual

lengthening of the intervals between interviews (to once every few months). The follow-up should be continued for at least two years. Contact with relatives should also be maintained after the patient leaves hospital, in order to provide support and advice about management. It is also important to inform all medical personnel concerned with the patient's care of the management strategy, especially the general practitioner. This will avoid the reintroduction of, or increase in, anticonvulsant medication and further unnecessary investigation should the pseudoseizures recur. It is best if the management is supervised by one person.

Should the patient prove unresponsive to the combined dynamic and behavioural psychotherapy approach, an alternative is to use a seemingly paradoxical procedure with the consent and co-operation of the relatives: the patient is informed that the fits are likely to continue unabated, since all attempts to understand and treat them have failed, and that their frequency may even increase. Because conventional treatment methods have been unsuccessful, strict bed rest with a minimum of sensory

stimulation is recommended: a bed with cot-sides in a single darkened room with only basic amenities and no books, television or visitors. The restrictions on activities and other amenities are systematically lifted as the seizure-free intervals lengthen, but are reimposed in reverse order should relapse occur. In resistant patients this simple behavioural approach can lead to a dramatic reduction or even abolition of seizures, but must be followed by continued supportive psychotherapy and work with key relatives.

The long-term outcome for pseudoepileptic seizures is still subject to debate and disagreement. Reported improvement rates have varied from 30–80% (Lesser, 1985). The widely differing views about progress probably reflect the nature of the unit the patient is referred to and the programme of management used. Having had personal experience of the management of a substantial number of such patients, it is my view that the majority respond to a carefully structured programme of psychological management. However, some may continue to react at times of stress with occasional clusters of pseudoepileptic seizures. A few remain a chronic problem.

Hysteria, Play-acting and Courage

DAVID C. TAYLOR

Levi-Strauss (1977) describes what happened to a child, in a primitive tribe, accused of sorcery—a crime punishable by death. The child invented more and more complex stories by way of self-justification. In the end his accusers believed his outlandish explanation because “the choice is not between this system and another but between this system and no system at all—chaos.” The child’s plight can represent the close affinity between magic and hysteria; his accusers might represent those contemporary psychiatrists who would prefer any system of classification of hysteria, however absurd, to no system at all (Sheehan & Sheehan, 1982a, b; DSM-III, 1980).

Commenting on similar issues, Mayou (1984) explained how lack of agreement and precise definitions cause great difficulties for psychiatry. Underlying the imprecision is a general failure to appreciate the importance of the fact that the different sicknesses to be classified are in different universes of discourse, and that any attempt to develop one system to embrace processes, things, and states of affairs is bound to fail (Taylor, 1979, 1982). Within this chaotic classification hysteria holds pride of place for ambiguity. Doctors wishing to dispose of the problem by abandoning the diagnosis, however, are mortified by the thought of how

otherwise to describe their next patient with those symptoms.

This mortification will persist until the concept of ‘hysteria’ is replaced by a better explanation. Some people believe that this will come from the biological sciences, others that it will come from psycho-social case analysis and epidemiological techniques. Some believe that if sickness is not physical it must be psychological, or again that if sickness is not physical it is not our business. I believe that hysteria is generated as a defence mechanism and propagated as a consensual phenomenon, as is magic. Like magic, it has no real properties beyond belief. Granted that it is a belief, the physiological and psychological characteristics of the believer are probably irrelevant. But beliefs, convictions and avowals, however, are powerful phenomena.

Hysteria persistently imposes itself upon medicine by threatening the implicit contract of trust between doctors and their patients. A group of people, referred to by Bayliss (1984) as ‘the deceivers’, pose problems not just of diagnosis but also of management, resource allocation and ethics. Having mentioned the Munchausen syndrome, illness by proxy and factitious disorders, but having studiously avoided the word ‘hysteria’, Bayliss remarked that “these patients are seldom malingerers” and that

"quite often, before the diagnosis is firmly established, an experienced psychiatrist will declare the patient as perfectly normal and unquestionably suffering from organic disease". This formulation, by a physician, is an important index of the contemporary standing of psychiatry as well as of hysteria and its group of inextricably associated phenomena. His point was that it is crucial for biomedicine not to be deceived, because it is potentially dangerous, wasteful and deprecatory.

Consider the emergence of a hysteria: a person in a predicament lays claim to sickness. This is probably a commonplace event, and can be regarded as tantamount to 'faints' (Daymas, 1982) or 'pax' in children's games. This particular claim, however, in this predicament, finds the opportunity for validation among the family or living group instead of being politely ignored or being offered temporary token regard. The sickness is now presented to the family physician; the physician attempts a rational validation, which naturally fails. If failure is an unacceptable outcome, a higher authority must be invoked. Since specialists specialise in organ systems, one system must be defined as 'sick' by the family doctor in order to identify the appropriate specialist. This process helps to refine the presentation, and of itself partly validates it. Rather than providing an elucidation, the specialist usually merely confirms or denies the putative disease. Not validating the disease does not invalidate the claim (Taylor, 1982); the patient still lays claim to it, since little alternative has been made possible. The medical view is that it must be due to 'something else', and if nothing else offers itself then 'hysteria' is the diagnosis that will be made.

Hysteria, the laying of claims to illnesses and diseases the presence of which cannot be corroborated, thus becomes in itself an illness. In effect, what doctors are saying is that claiming to be sick when not sick is a variety of sickness. However contradictory that may seem, doctors feel justified in that belief by the manifest distress that can be evident in the original predicament and the subsequent development of the sickness. What we have hitherto lacked the courage to say is that a good deal of sickness is attributable to the enactments of distress and the playing-out of scenarios in which people exhibit distress through whatever scope is left to them. The body speaks what the tongue cannot utter. From this common situation, without any useful reference to physical or mental illness, some people are led astray and persuaded into severe sickness.

The alternative viewpoint, dignified by a thousand years of medical tradition, is to treat hysteria like any other sickness. For example, Breuer (1895)

regarded it as "a clinical picture which has been empirically discovered and is based on clinical observation in just the same way as tubercular pulmonary phthisis". This is a false postulate, because 'clinical pictures' are not in the same universe of discourse as 'pulmonary tubercles'. It leads to the false proposition that the cause of hysteria will be found by detailed investigation of people deemed to be sufferers, in much the same way as is tried for schizophrenia and was successful for *Legionnaires' disease*.

My most frequent connection with hysteria comes from young people who are persuaded that they suffer from epilepsy and wish to encourage others to the same belief. They are identified to me by their partial success, for if they failed or completely succeeded I should not notice them. The difficulty to which they give rise was characterised by Worster-Drought (1934): 'It is extremely difficult, in fact almost impracticable, to draw a hard and fast line between hysteria and epilepsy'. His paper was written just before the advent of EEG, at the watershed of ancient and modern epileptology.

Since 1934, the late 19th century concept of epilepsy as an electrical discharge from neurones spreading by progressive recruitment has been vindicated and developed down to neurochemical levels. With hysteria, however, we have been encumbered with ideas based on psychic energy, or flux, which might be blocked, diverted, or converted; these ideas have led nowhere. The contrast might be seen as an aspect of the relative failure of psychiatry, but it is more usefully seen as suggesting that hysteria is not biomedical in nature. This does not mean that it does not exist at all. As Widlocher (1982) wryly noted: "The last trick that the Great Neurosis plays on medicine will be to slip away down the rift caused by the separation of neurology from psychiatry". Hystero-epilepsy is a way of acting in a way which makes people wonder if one is having a fit. Most people who do this really are having a fit. They see doctors who believe them and investigate them for disease.

But 'disease' is only one component of sickness, which is also composed of 'illnesses' and 'predicaments' (Taylor, 1982). These terms owe something to Karl Popper's conception of three worlds (Popper & Eccles, 1977) to which we attend; world I, a world of material bodies or 'things'; world II, a psychological world of mental states; and world III, a world of human artefacts such as novels, plays, and enactments, which although abstract are equally real. 'Illnesses' cover most of the psychiatric disorders (world II), and 'predicaments' are those situations which are human constructs which can be

seen as excruciatingly painful and problematic (world III).

There is little evidence to support the idea of psychopathology in children with hysterical symptoms, so there is little to suggest that the explanation of hysteria will prove to be in world II. I think that hysteria is a world III phenomenon – an artefact like a story or play, a fictive consensual belief. This is easiest to understand in the ‘mass’ hysterias which are frequently reported throughout the world (Small & Borus, 1983; Mohr & Bond, 1982; Dhadphale & Shaikh, 1983). It is ludicrous to suppose that personal psychopathology predisposes the actors in these dramas in any meaningful way. It does not mean that the effect is trivial: nine hundred people were persuaded to commit synchronous suicide by James Jones in Guyana. Even in the most trivial incidents there are always some who are reluctant to relinquish their new convictions. The forms and the victims, the situations and the causal explanations are so regular as to have the air almost of a ceremony (McEvedy & Beard, 1970). It is just more difficult to see the social and group dynamics which produce the individual cases. The casting and the auditioning have occurred elsewhere, and in secret. Even more importantly, when sickness emerges in an individual it is not necessarily realised that it is a World III phenomenon, and the social group, as well as physicians, will quite properly regard it at first as being in World I: a potential disease.

The problem is that the enactments may come from the depths of the behavioural repertoire, from protective and adaptive mechanisms which we share with other animals. Many ground-nesting birds such as the curlew will lure birds of prey away from attacking their young with a display of feigned incapacity. Kretschmer (1961) perceived a range of reactions by which animals effect their own removal from overwhelming stress. One, translated as ‘violent motor reaction’ (Kretschmer, 1926) or ‘instinctual flurry’ (Kretschmer, 1961), describes uncoordinated frantic attempts to flee. It is typified by the behaviour of a bee or a bird in a room, or people at the scene of a disaster. Another is the ‘death feint’ or ‘playing possum’. These are allaesthetic displays designed to alter the behaviour of other animals. *Peromyscus* (the deer mouse), for example, maintains in a small proportion of its population a gene for convulsing if shaken, which helps reduce risk from predators. (Chance & Russell, 1959). Neither of these ‘hysterical’ reactions is entirely without risk; ill-organised attempts to escape disaster may carry a survivor towards rather than away from danger, and ‘playing possum’ or ‘playing hurt’ may occasionally just make things easier for the predator. The study

of these important reflex defences provides the best option for biomedical study of hysteria, but they are probably biomedically transient and ‘hysteria’ is suffered by people who have become caught up in an extended enactment.

In man, these behaviours may be interpreted as ranging from the reflex to the contrived. As such, they are subject to moral evaluation. They are judged more or less negatively depending upon the degree to which they seem personal to the patient and demanding of others, or are desirable and clearly consensual beliefs. At one end of the scale, extreme deliberate abuse of the ill-health system is called malingering; at the other, placid concurrence with therapeutic intent is called a placebo response. Being persuaded is more or less reflexic. A mother who had abused her child was speaking to social workers while her infant was screaming beside her. She raised the infant to within inches of her face and bellowed “Shut up”. The child lapsed immediately into a stupor which lasted several hours. This is an extreme case of the well-known phenomenon of an ‘over-tired’ child lapsing suddenly into sleep at a sharp remonstrance. Similar reactions have been described in people who have just been told that they have cancer (Beecher, 1962; Milton, 1973; Stedeford, 1984). At their extreme they bring us back to magic and to hystero-epilepsy.

Cannon (1942), in his article on voodoo death, quoted Basedow (1925): “... the expression on his face becomes horribly distorted ... He attempts to shriek, but the sound chokes in his throat, and all that one might see is froth at his mouth. His body begins to tremble and the muscles twist involuntarily ...”. The victim is persuaded to die. It is a consensual phenomenon, because everyone knows that he will die and they withdraw their social support. (What if the social supporters ‘know’ that someone is ‘ill’?) Cannon observed that one of the interesting characteristics of this mode of dying was its astonishing reversibility from states near to death, given adequate counter-suggestion. The important finding relevant to hysteria is that those who have recovered from these states say that they did not wish to die but recognised that they had been victims of forces which had made death inevitable. Cannon adds: “the phenomenon is characteristically noted among aborigines – among human beings so primitive, so superstitious, so ignorant that they feel themselves bewildered strangers in a hostile world.” I suggest that he meant they were child-like, in an animistic phase of personal as well as cultural development, under the influence of others more powerful – rather like Charcot’s patients in the Salpêtrière.

This view of hysteria turns upon persuasion: the

strength of the persuasive forces, the liability to be persuaded, the capacity to engage in the drama, and the effectiveness of the escape. In it 'conversion' is appropriate in its religious rather than its Freudian sense. It may serve a purpose, or it may be a trap; it may be transient, or it may ensnare. The sorts of extreme situations described by Woodruff *et al* (1982) imply people having been trapped into a life of hysteria, just as other people are trapped into living through epilepsy or other chronic sicknesses.

The elements of an hysteria are discernible in most serious writing on the subject, but deserve to be clearly stated. The first requirement (Taylor, 1979, 1982) is a predicament which is intolerable but for which all apparent solutions are blocked. The traditional example of this, from Freud's own observations, follows sexual abuse, but there are equally painful alternatives. The predicament, or the blocked solutions, may concern the psychopathology of the 'hysteric', but in childhood hysteria most authors now agree that little abnormality is detected (Dubowitz & Hersov, 1976; Maloney, 1980; Goodyer, 1981). Secondly, an ally who is helping to promote the sickness is required. This person acts like a manager; he too may have been innocently trapped, or else have his own psychopathology. Allies may believe only in world I sickness, quite justifiably deny world II problems, and have no conception of world III. These allies will vigorously defend the 'right to be sick', and pursue disease explanations relentlessly. Thirdly, a model of the sickness has to be available, whether current or historical, real or contrived, chronic or ephemeral. Thus one patient who twitched in a faint on being given an injection to protect her against sicknesses of equally uncertain provenance was asked if there was epilepsy in the family. (Taylor, 1985). Finally, hysteria can only be promoted by persons with the necessary social skill or by those who derive that skill through their allies. This con-

straint, among others, precludes young children from hysteria and probably defines the border with malingering and Munchausen's syndrome.

Doctors in particular, and other health care workers to some extent, can provide well for all these elements. They can block alternative explanations by patients, or by failing to take an adequate history of their predicament fail totally to discern it. They are powerful allies in sickness promotion, and can be sucked into the system quite unwittingly, especially if they have an investment in a biomedical diagnosis. They provide a variety of models and can offer suggestions which improve the credibility of the sickness. They have the requisite social skills. They are consistently intermittently reinforced in their belief in the organic substrates of hysteria (Slater, 1965) by the literature and by their own experience. They seem never to have been told that the emergence of organic disease in no way invalidates the hysteria, which often uses a different body system and in any case is a phenomenon in a different domain. It needs courage for physicians to help their patients most by making a decision on the balance of benefit, not to exclude every possible organic cause for a sickness.

This view of hysteria is similar to part of that recognised by Kretschmer (1926), Rabkin (1964), Kendell (1982) and Slater (1982), and well argued by Mayou (1975). Their view is that hysteria is a social construction set up in the doctor-patient relationship. Hysteria, the laying claim to sickness for which there is no objective evidence, is a commonplace reaction, and those who become dignified by a formal diagnosis are a severe, extreme, or fortuitous selection. Treatment requires detailed analysis of the predicament, negotiation with the allies, uncovering of the model (especially from fantasy), and the selection of a dignified alternative by a figure powerful enough to alter firmly rooted beliefs.

A Controlled Assessment of Propranolol in the Treatment of Neuroleptic-Induced Akathisia

LENARD ADLER, BURT ANGRIST, ERIC PESELOW, JUNE CORWIN, ROBERT MASLANSKY and JOHN ROTROSEN

Twelve patients with neuroleptic-induced akathisia were treated in a randomised, double-blind, cross-over design with propranolol and matching placebo. Propranolol caused significant decrements in both subjective and objective ratings of akathisia, but not in anxiety scores. This confirms prior findings of the efficacy of propranolol in akathisia induced by neuroleptic treatment.

Akathisia is a frequent and often disturbing side-effect of neuroleptic therapy; its literal translation is an inability to remain seated (Braude *et al*, 1983; Raskin, 1972). It occurs most frequently with high-potency neuroleptics, but can occur with any of these agents. Braude *et al* delineated mild, moderate, and severe forms of the syndrome. In mild akathisia, the symptoms are mainly subjective in nature and involve an uneasiness and inner restlessness, more often sensed in the legs. In addition to these complaints, patients with moderate akathisia have: rocking from foot to foot, walking in place, a coarse tremor, and myoclonic jerks in the feet. The severe form further involves an inability to maintain one's position, also known as *tasikinesia*; this leads to frequent arising from a seated position or pacing.

The frequency with which akathisia occurs is between 12.5% (Freyhan, 1958) and 45% (Van Putten, 1975); the most common estimate of prevalence is about 20% (Braude *et al*, 1983; Ayd, 1961; Marsden & Janner, 1980). The symptoms of akathisia can be so distressing as to hinder compliance with treatment or exacerbate psychopathology (Van Putten, 1974).

The treatment of akathisia is often difficult. Therapeutic approaches include: anticholinergic medications (Van Putten, 1974, 1975), benzodiazepines such as diazepam (Donlon, 1973; Gagar *et al*, 1978) and lorazepam (Germino, 1985), and the anti-parkinsonian drug amantadine (DiMascio *et al*, 1976). Clinically, these treatments are often only partially effective and, particularly with anticholinergics, side-effects frequently limit the dose. However, recent evidence indicates that beta-adrenergic blocking medication can be effective. Lipinski *et al* (1983, 1984) and Zubenko *et al* (1984) have reported open studies in which propranolol, a beta blocker

with both central and peripheral effects, in low doses (30-80 mg/day) led to marked improvement of akathisia. We have also found, in a prospective, single-blind study, that propranolol (20-30 mg/day) was superior to lorazepam (2 mg/day) (Adler *et al*, 1985). Ratey *et al*, (1985) have also described several patients in whom this condition was effectively treated with nadolol, a beta-adrenergic blocking drug with mainly peripheral effects.

To further examine the effect of beta blockers on akathisia, we conducted a randomised, double-blind study of propranolol.

Method

In-patients and out-patients receiving neuroleptics, who had akathisia-like movements, were identified. Patients were enrolled if these movements were of sufficient intensity to be rated at least '1' on a modification of the original Simpson/Angus EPS Scale (Simpson & Angus, 1970) ('Mild; occasional restlessness observed during examination and/or subjective report of definite restlessness'). A physical examination and ECG were done; patients were excluded if they had any contraindication to receiving beta blockers, such as asthma, insulin-dependent diabetes mellitus, or any cardiac conduction abnormality or concurrent cardiovascular illness which required medical treatment.

Patients were randomised to a 6-10 day treatment period with either propranolol, in 10 mg capsules, or matching placebo. The initial dosage was one capsule twice daily; the maximal daily dosage was six capsules. Side-effect monitoring, blood pressure assessment, and adjustment of the dose of medication were carried out for several days into the treatment period. At the end of this period, side-effects and blood pressure were again assessed and akathisia ratings were carried out. Patients were then crossed over to the alternate medication, with treatment and assessment as in the first stage. Neuroleptics and anti-

TABLE I
Characteristics of patients

Age	Sex	Diagnoses	Medications	Maximum dose of propranolol
35	M	Schizophrenia	Perphenazine 32 mg/day Benztropine 4 mg/day	20 mg
35	M	Bipolar affective disorder, depressed; alcohol dependence; grand mal epilepsy	Perphenazine 56 mg/day Trihexyphenidyl 4 mg/day Diphenylhydantoin 400 mg/day Lithium carbonate 1800 mg/day	40 mg
32	F	Schizophrenia	Fluphenazine decanoate 62.5 mg every 10 days Fluphenazine 15 mg/day Trihexyphenidyl 6 mg/day	60 mg
44	M	Schizophrenia	Fluphenazine decanoate 200 mg every 7 days Fluphenazine 5 mg up to 6 hourly p.r.n. Trihexyphenidyl 8 mg/day Temazepam 30 mg node p.r.n.	60 mg
40	F	Schizophrenia	Fluphenazine decanoate 125 mg every 10 days Haloperidol 5 mg up to 3 hourly p.r.n. Trihexyphenidyl 8 mg/day	60 mg
23	M	Schizophrenia	Chlorpromazine 400 mg/day	60 mg
34	M	Schizophrenia	Fluphenazine decanoate 37.5 mg every 7 days Fluphenazine 5 mg daily p.r.n. Trihexyphenidyl 8 mg/day	40 mg
33	M	Schizophrenia; alcohol dependence	Perphenazine 112 mg/day Temazepam 30 mg node p.r.n.	20 mg
39	M	Schizophrenia	Fluphenazine decanoate 62.5 mg every 7 days Diphenhydramine 150 mg/day Trihexyphenidyl 15 mg/day	60 mg
43	F	Schizophrenia	Fluphenazine 30 mg/day Benztropine 6 mg/day Lorazepam 1 mg node p.r.n.	60 mg
29	M	Schizophrenia	Fluphenazine decanoate 25 mg every 7 days	60 mg
26	M	Schizophrenia	Perphenazine 52 mg/day Amantadine 400 mg/day	50 mg

parkinsonian medications were held constant throughout the trial. Both doctors and patients remained blind to the order of treatments.

Assessments of akathisia and anxiety were performed at baseline and on the last day of each treatment period. These consisted of: (1) the Simpson/Angus EPS scale (the objective rating); (2) a subjective rating in which the subject was asked to mark a 100-millimetre line corresponding to perceived restlessness; and (3) the Hamilton Anxiety Scale (HAS). All subjects gave informed consent.

Results

Twelve subjects participated; their ages, sex, neuroleptics, diagnoses, anti-parkinsonian medication and final dose of propranolol are shown in Table I. The mean number of capsules per day was 5.1 for propranolol and 5.3 for placebo. The final HAS rating during propranolol treatment was not obtained on one patient.

Six of the 12 subjects received placebo first; the remaining six were initially treated with propranolol. Baseline

TABLE II
Ratings at baseline and on last day of treatments

	Baseline	Mean (S.E.M.) Propranolol	Placebo
Objective* akathisia	1.75 (0.13)	0.75 (0.18)†	1.50 (0.23)‡
Subjective** akathisia	56.0 (5.0)	22.8 (5.0)††	45.3 (7.1)‡‡
Anxiety***	11.8 (1.6)	9.6 (2.0)	11.7 (2.0)

*Clinical ratings for pooled sample ($n=12$), statistical analyses by ANOVA for completely repeating measures with rating period and drug as repeated factors. *Post hoc* planned comparisons made by paired *t*-tests

*Overall: $F(2,22)=13.00$, $P<0.001$

†Propranolol vs baseline: $t(11)=5.74$, $P<0.0001$

‡Propranolol vs placebo: $t(11)=3.45$, $P<0.006$

‡‡Placebo vs baseline: $t(11)=1.15$, N.S.

**Overall: $F(2,22)=13.74$, $P<0.001$

††Propranolol vs baseline: $t(11)=5.87$, $P<0.0001$

‡‡Propranolol vs placebo: $t(11)=3.15$, $P<0.009$

‡‡‡Placebo vs baseline: $t(11)=1.64$, N.S.

***Overall: $F(2,21)=1.31$, N.S.

scores were similar in both of these groups; order of treatment did not significantly affect akathisia or anxiety ratings (Student's *t*-test (independent), all $t<1$). Therefore, statistical tests were performed on the pooled sample of 12 subjects (Table II).

Data were analysed by repeated measures analyses of variance (ANOVA), with rating period and drug (propranolol and placebo) as the repeated factors, to control for multiple, non-independent comparisons. *Post hoc* planned comparisons were performed by paired *t*-tests.

Propranolol caused a significant overall improvement in both objective and subjective ratings of akathisia. This effect was due to significant decrements in akathisia ratings on propranolol versus ratings done both at baseline and on placebo. Placebo caused no significant change of akathisia

ratings from baseline. No significant effect of either propranolol or placebo was seen in HAS. Statistical comparisons are shown in the legend to Table II.

Ten of the 12 patients were able to select the active medication, and indicated that they preferred it (one patient could not discriminate between the treatments and one believed that placebo was the active medication). This result was significant by the test for significance of a proportion ($Z=2.29$, $P<0.05$). There were no significant differences in the nine EPS measures other than akathisia after treatment with propranolol versus after placebo treatment. Mean arterial pressures during treatment with propranolol (97 ± 3 mm Hg) and with placebo (100 ± 3 mm Hg) did not significantly differ.

Discussion

The results of this double-blind, placebo-controlled, cross-over study confirm that propranolol in doses of 20–60 mg/day is an effective treatment of neuroleptic-induced akathisia. Efficacy was further suggested by the fact that most of the patients were able to select and indicated they preferred the active medication. Furthermore, six patients requested and have received propranolol as a maintenance medication, and have not since experienced a return of their akathisia. As in prior studies by Lipinski *et al* (1983, 1984), Zubenko *et al* (1984) and ourselves (Adler *et al*, 1985), propranolol in this dose range did not significantly affect mean arterial pressure.

Anxiety is often considered to be part of the akathisia syndrome. However, the fact that propranolol improved akathisia ratings, but did not affect anxiety ratings suggests that akathisia and anxiety may be dissociated.

Further investigations as to the central and peripheral effects of beta-blockers may clarify the role of dopaminergic and beta-adrenergic systems in neuroleptic-induced akathisia and perhaps in other conditions where motor restlessness is a problem.

The Prediction of Abnormal Evoked Potentials in Schizophrenic Patients by Means of Symptom Pattern

H. B. ANDREWS, A. O. HOUSE, J. E. COOPER and C. BARBER

The case notes of 23 schizophrenic patients who participated in a study of somato-sensory cortical evoked responses were examined for descriptions of the clinical features of their mental state at the time of first illness or most recent relapse. A comparison of syndrome scores derived from Present State Examination with those derived from case notes showed that the latter was a reliable method of mental state description for the purposes of this study. A group of syndromes similar to that described in electrodermal research was identified from the case note review and found to be highly correlated with the presence of an abnormal response in the somato-sensory evoked potentials study.

In a recent paper, Gruzelier & Manchanda (1982) suggested that two syndromes of schizophrenia could be identified which correspond to two types of asymmetrical electrodermal activity following auditory orienting stimuli. They proposed that these two syndromes occur as a result of differential over- and under-activity of the two cerebral hemispheres, so that left hemisphere overactivity produces a florid, delusional and hypomanic clinical picture, while right hemisphere overactivity produces a slow, withdrawn and self-neglected clinical picture. We investigated whether these two syndromes could also be found in a group of schizophrenic patients in a study of somato-sensory cortical evoked potentials.

The design of the evoked potential study, and the methods and equipment used are described in greater detail elsewhere (Cooper *et al*, 1985). Briefly, the cortical potentials were evoked by a percussive stimulus to each index finger by means of a modified loud-speaker cone, recorded from the vertex and over each parietal lobe 2 cm posterior and 6 cm lateral to the vertex, and averaged over either 512 or 1024 stimulus presentations. All electrodes were referenced to linked ears, and the audible click from the stimulus apparatus was masked by popular music played through headphones for the duration of the experiment. The recording epoch was the first 100 ms post-stimulus, and in each case it was demonstrated that the order of stimulus presentation had no effect on the potentials recorded, and that the auditory mask was effective.

The expected pattern of evoked responses from such a stimulus in the first 100 ms is that the parietal cortex contralateral to the stimulated finger is activated, and that little, if any, activity is recorded over the ipsilateral cortex. This expected lateralisation

of response was lost in about half of the 21 schizophrenic patients reported in our previous study (Cooper *et al*, 1985), but was not lost in either the manic depressive patients or the normal volunteer comparison group; this suggested that those schizophrenics with the clearly abnormal response may be different in some clinically relevant aspect of their illness. The earlier paper reported a trend associating the abnormal response with a poorer clinical outcome. In this paper, we report the results of testing the hypothesis that the syndromes derived from the Present State Examination (PSE) (Wing *et al*, 1974) which characterise the right hemisphere-overactive syndrome described by Gruzelier & Manchanda (1982) are associated with the abnormal evoked potential response. The reasons for deciding to test this association were firstly that those right hemisphere-overactive syndromes (slowness, self-neglect and withdrawal) are likely to be correlated with the poorer social outcome that had already been noted; and secondly, if two different electrophysiological measurements can be shown to correlate with a clinically salient distinction between two presentations of schizophrenia, then they might be produced by the same underlying physiological abnormality. Such a straightforward correlation between two different measures would have both diagnostic utility and a number of research implications.

Method

Subjects

The patients described are 23 out of 24 with a clear and unequivocal diagnosis of schizophrenia who participated in an on-going study of somato-sensory cortical evoked

TABLE I

Ages and hospital admissions for patients in the SSEP study

	Male	Female

Range	53-18	44-17
Average number of admissions*	4.6	4.1
Average total months in hospital†	11.4	6.4

*Excluding one male with 17 brief admissions.

†Excluding rehabilitation admissions of more than one year (one male & one female).

potentials (SSEPs). Our findings in the first 21 patients studied are reported elsewhere (Cooper *et al.*, 1985). The 24th patient lacked sufficiently detailed clinical documentation and was excluded for that reason.

The group comprised 12 men and 11 women, whose ages and hospital admissions are shown in Table I; the men were older at the time of recording and had spent more time in hospital. Two patients were adopted male monozygotic twins, and two were father and son. Of the remaining 19, four had a history of severe mental illness in a first-degree relative: schizophrenia in the case of two, manic depression in another, and unspecified psychosis in another.

In this group, 16 patients had the abnormal response (either bilaterally or unilaterally symmetrical) and seven had the normal response (bilaterally asymmetrical). The types of response are reported and discussed elsewhere (Cooper *et al.*, 1985).

Experimental design

In outline the study had four stages: firstly, two clinical syndrome categories were outlined, and category scores for

each patient were obtained from case note ratings; secondly, the case note ratings were compared for reliability with separately obtained PSE ratings in some of the patients; thirdly, the category scores were used as the basis for a blind prediction of abnormality of SSEPs; and fourthly, an association between certain clinical syndromes and SSEP abnormality was sought. These stages are outlined in greater detail below.

Derivation of the syndrome ratings from the case notes: The items and factors described by Gruzelić (1983) were translated into the nearest equivalent PSE syndromes of which they form a whole or part. This essentially involved using the terminology of PSE syndromes to describe the clinical phenomena under consideration, in a similar manner to that used in the derivation of the Syndrome Check List (Wing *et al.*, 1974). The syndromes were grouped to produce two 'categories', approximating to Gruzelić's left hemisphere-overactive syndrome (Category 1) and the right hemisphere-overactive syndrome (Category 2). These categories are designated 'active' and 'withdrawn' respectively, for the purpose of further discussion (Table II).

The psychiatric case notes of all 23 patients were examined by one of us (AOH, an experienced and trained PSE interviewer), and the presence or absence of these PSE syndromes in a substantial part of the index illness was recorded, as in the Syndrome Check List. The rating of the presence or absence of each syndrome in each patient was undertaken blind to the SSEP results, and blind to the PSE-derived syndrome scoring.

Reliability of the case note-derived ratings compared to PSE interview-derived ratings: Nine of the 23 patients had PSE interview-derived data for the index illness, made for other reasons, the percentage agreement between the ratings from the two sources was calculated as a way of assessing the reliability of the case note ratings. The PSE interviews and ratings had been undertaken before the present study was started and were therefore blind to the purpose of this study and to the SSEP findings.

TABLE II
PSE Syndrome list used in case note review of 23 schizophrenic patients

Category 1	PSE mnemonic	Category 2	PSE mnemonic
Hypochondriasis	HY	Neglect	NG
Depressive delusions	DD	Affective flattening	AF
Grandiose delusions	GR	Slowing	SL
Hypomania	HM	Lack of energy	LE
Overactivity	OV	Social unease	SU
Ideas of reference	IR	Simple depression	SD
Situational anxiety	SA	Specific features of depression	ED

FIG. 1 The percentage prevalence of "active" syndromes in schizophrenic patients with normal and abnormal SSEPs. For abbreviations see Table II.

FIG. 2 The percentage prevalence of 'withdrawn' syndromes in the two groups. For abbreviations see Table II.

Prediction of the type of response in the individual patient: Each syndrome was scored '1' or '0', depending on its presence or absence in the case note record, and these amounts were added up to give the number of syndromes present in the two categories for each patient. Where there were more 'withdrawn' category syndromes present than 'active' category syndromes, an abnormal response was predicted. The predictions were made by AOH, blind to the actual SSEP results.

Correlation between SSEP-type and the syndrome category scores: The percentage prevalence of each syndrome in the two categories for both the normal and the abnormal responders was estimated (Figs 1 and 2). Differences were calculated between the patient groups (abnormal responders $n=16$, normal responders $n=7$) in terms of their total category scores, and between the percentage prevalence of the individual syndromes across the two groups.

Results

Comparison of the case note and PSE interview ratings

There was less than 70% agreement on only four syndromes, self-neglect and ideas of reference were more commonly rated as present from the case notes; lethargy and poor concentration were more commonly rated as present in PSE interviews.

The discrepancies are not large and may be easily explained. For instance, self-neglect is more likely to be recorded in case notes than rated as present during the PSE interviews because of the more prolonged period of observation involved in the former; ideas of reference, which are largely situation-dependent and evanescent, may be present in the ward environment but not in the interview room; lethargy and loss of concentration are symptoms elicited at PSE interviews, often with no expression in behaviour that may be observed in the ward, and hence are likely to be under-recorded in case notes.

The prediction of SSEP abnormality

In two patients, no prediction was made because the scores in each category were the same. The abnormalities were predicted correctly in 19 of the 21 cases in which a definite prediction could be made (Fisher's exact test two-tailed, $P=0.002$; Table III).

SSEP type and syndrome category scores

Patients with abnormal SSEPs had significantly different 'active' and 'withdrawn' category scores (Wilcoxon matched-pairs test, $t=3$, two-tailed, $P<0.05$). They also had significantly higher 'withdrawn' category scores (Wilcoxon matched-pairs test, $t=3$, two-tailed, $P<0.01$). Abnormal responders were more likely to have three or more 'withdrawn' syndromes each, while normal responders were more likely to have less than three (Fisher's exact test, two-tailed, $P<0.05$). The syndrome

TABLE III

Comparison of actual and predicted results of somatosensory evoked potentials (SSEP) in 23 schizophrenic patients

Actual results of SSEPs	Predicted results of SSEPs from category scores		
	Abnormal	Normal	Equivocal
Abnormal	14	0	2
Normal	2	5	0
Equivocal	0	0	0
Total	16	5	2

'social unease' (SU) and the syndrome 'slowness' (SL) were significantly more common in the patients with abnormal SSEPs (Fisher's exact test, two-tailed, $P < 0.05$ in both cases).

Discussion

Although the number of patients in this study is small, it has been possible to demonstrate a correlation between a physiological abnormality found in some schizophrenic patients and certain features of their mental state. The features which we have found to be relevant show similarities with those highlighted in the 'right hemisphere-overactive' syndrome of Gruzelier & Manchanda (1982). Any discrepancies may be explained by differences in the selection of patients and in the instruments used for clinical description. The main difference between our syndrome groupings and those of Gruzelier & Manchanda appears to lie in the lack of discriminating power of the depressive syndromes (Figs 1 and 2). As clinical practice suggests that PSE depressive syndromes may represent a non-specific dysphoria, associated with many varieties of major mental illness, it is not surprising that they cannot be readily associated with electrophysiological abnormality.

A corresponding ability to identify a syndrome grouping equivalent to Gruzelier's left hemisphere-overactive has not been demonstrated—perhaps because the 'active' and hypochondriacal syndromes are rare in the evoked potential group, while ideas of reference, depressed mood and anxiety are too widespread to be of discriminating value.

The syndromes associated with the evoked potential abnormality in this study are closely related to the descriptions of the primary symptoms of schizophrenia given by Bleuler (1911), and it is of interest that Gruzelier refers to the distinction pro-

posed by Kety (1980) between 'classical Bleulerian schizophrenia' and 'acute functional psychosis', when discussing the possible clinical relevance of his electrodermal study. The 'withdrawn' category also bears comparison with the features of 'true' (poor prognosis) schizophrenia, as suggested by Langfeldt (1960): blunting, lack of initiative, altered behaviour and motor disorder.

Although the 'withdrawn' syndromes are generally considered part of the clinical poverty syndrome, and therefore indicators of poor outcome, their intensity can vary considerably (Hirsch *et al*, 1973). The evoked potential abnormality bears no relation to the presence or absence of these or any other syndromes at the time of recording; it is their presence characterising the patients' mental state when ill which gives the 'withdrawn syndromes' their predictive value. Indeed, since the evoked potential abnormality is stable over time and mental state is not, it could not be otherwise. If confirmed in other studies, this suggests that the SSEP abnormality is an indication of a persisting vulnerability, which disposes towards a certain sort of mental state when ill, and towards a certain kind of outcome.

As the correlation between syndromes and physiological abnormality which was found in this study is similar to those found following investigation of different physiological parameters, it is reasonable to speculate that the physiological abnormalities are themselves related. The accumulating evidence for intra- and interhemispheric disorganisation, and for abnormalities of cortical arousal has been reviewed recently (Walker & McGuire, 1982; Gruzelier, 1983; Flor-Henry, 1983). The difficulty in discussing the relationship between hemispheric arousal, hemispheric disorganisation and early SSEP abnormalities rests principally on the uncertainty as to which cortical or subcortical disorder might produce them. However, a brief discussion of general cortical-subcortical relationships is worthwhile.

The sensory volley from the stimulus apparatus used in the SSEP recording is likely to be produced by muscle spindle activity as a result of the percussion from the cone of the loudspeaker (Pratt *et al*, 1979). The earlier of the two peaks we identified is generally considered to be the arrival of the first thalamic component at the primary receiving area (Allison *et al*, 1980). By 80 ms post-stimulus, the activity at the two parietal recording sites tends to equality; there is no suggestion of a persisting abnormality of cortical activation at those sites after the second peak which we identify at 50 ms has passed. The relevance of this early cortical abnormality to any later cortical abnormalities that may reflect handling of higher

order sensory information is uncertain. However, the fact that there is a bilateral component, one to each receiving area from the thalamus, suggests some disorder of thalamo-cortical interaction where the cortex ipsilateral to the stimulated finger is activated by the thalamus, as well as the more normal contralateral activation. The mutual inhibition of the hemispheres by each other is a well established feature of the large-scale control of cortical activity (Geschwind, 1965), and it is not unreasonable to suppose that hemispheres which are abnormally bilaterally activated by somato-sensory thalamic volleys continue to inhibit each other in the usual way. The early abnormalities described here may be taken to be produced by some disorder of thalamo-cortical interaction, which may, in its turn, produce the overactive hemispheres that are described in electrodermal and dichotic listening studies.

The reasons for considering that abnormalities in visual cortical evoked potentials may be produced by abnormal cortico-thalamic activity are discussed by Jutai *et al* (1984). This and the finding of a loss of the normal lateralisation of auditory evoked potentials in a proportion of schizophrenics reported by Connolly *et al* (1985), taken together with the results reported here, suggest that the explanation of the difference between normal and schizophrenic evoked potentials across the sensory modalities may be due to the presence of a general disorder of cortical—sub-cortical relationship, rather than of a disorder specific to any one sensory modality. The possibility that such abnormal relationships may be of relevance in schizophrenia merits further investigation.

The Formation of Maintenance of Delusions: A Bayesian Analysis

D. R. HEMSLEY and P. A. GARETY

This paper argues that recent research on normal-belief formation is relevant to our understanding of the establishment and maintenance of delusions. Bayesian theory provides a normative model of the way in which evidence relevant to normal beliefs may be evaluated: this makes it possible to classify delusional beliefs in terms of deviations from optimal Bayesian inference. Some hypothetical forms of deviation appear to correspond closely to cognitive processes observed in some groups of deluded patients. Theories of the precise nature of the abnormal judgemental processes also have implications for psychological approaches to treatment of deluded patients. The role of hallucinations in the formation and/or maintenance of delusions and the extent to which the distortions of cognitive processes associated with delusions are content-specific or mood-specific are also considered.

This article aims to indicate ways in which a recent paper on the formation of *normal* beliefs (Fischhoff & Beyth-Marom, 1983) may aid our understanding of the establishment and maintenance of *abnormal* belief systems (delusions). We also argue that a consideration of such literature suggests a number of experiments to clarify the nature of abnormal beliefs.

Although, in a general sense, delusions may be viewed as abnormal beliefs, the definition of "delusion" continues to present problems. Mullen (1979) has suggested that abnormal beliefs have the following characteristics:

- (i) They are held with absolute conviction
- (ii) They are experienced as self-evident truths, usually of great personal significance
- (iii) They are not amenable to reason, or modifiable by experience
- (iv) Their content is often fantastic or at best inherently unlikely
- (v) The beliefs are not shared by those of a common social or cultural background (Mullen, 1979, p. 36).

The difficulties inherent in such standard definitions have been examined by Moor & Tucker (1979). Even individually the criteria present problems; in conjunction, the definition becomes further confused. We hope to clarify the issues involved by an examination of the various ways in which the processing of information by deluded subjects may deviate from normality.

It appears to be essential to distinguish between the

establishment and the maintenance of belief systems. Establishment may result from abnormal perceptual experiences, such as previously ignored and/or preconscious information becoming salient (Frith, 1979). Authors have differed in their assessments of the role of anomalous experiences in the formation of delusions. Some, such as Maher & Ross (1984), have argued that the processes whereby the beliefs are formed are normal. In their theory, a normally-formed belief corresponds to a Jasperian "secondary delusion" (Jaspers, 1913) which is explicable in terms of the patient's background, personality or experiences: it is distinguished from a "primary delusion" which is not understandable and represents a disturbance of symbolic processing or attribution. Winters & Neale (1983) note that this distinction between explicable and inexplicable beliefs is not generally accepted or reliable, and question its validity as a diagnostic marker.

It may also be argued that normal processes are involved in the *maintenance* of abnormal beliefs, it being apparent that even "normal" strongly held beliefs are highly resistant to change. Here one is forced to confront the question of whether the statement "strong beliefs are resistant to change" is a tautology. The problem obviously lies in the definition of "strong belief", which involves both resistance to change and certainty of belief. In addition, resistance to change may be specified either in terms of the likelihood of spontaneous alteration of the belief, or in terms of the effects of confrontation with evidence inconsistent with the belief. Clearly we need to examine the relationship between resistance to change and initial intensity of belief, and to

ascertain whether this is different for abnormal and normal beliefs. If the relationship were identical, this would support the view that normal processes may be involved in the maintenance of delusions: it would then be important to examine how, when and why strong beliefs are formed, rather than why they are difficult to change.

The alternative position is that the processes which maintain delusions are abnormal. Cameron (1951) has suggested that deluded individuals disregard information incongruent with their delusional systems. However, as a paper by Alloy & Tabachnik (1984) indicates, similar processes are operative in the maintenance of *normal* strongly held beliefs. Alloy & Tabachnik consider organisms' ability to detect the relationships or covariations among stimuli, behaviour and outcomes in the environment: information about such covariation provides a means of explaining the past, controlling the present, and predicting the future. They propose that this "covariation perception" is determined by the interaction between two sources of information: (a) the organism's prior expectations about the covariation between two events; and (b) current information provided by the environment about the objective contingency between events. The relative impact of each factor is dependent on the strength of the other: the same level of current information regarding covariation of events has less influence on an organism's perception of contingency when the organism has strong prior expectations about the relationship between the events. Thus if deluded subjects take little account of information incongruent with the delusional system, this may simply reflect strong prior expectations.

A normative theory of how people *should* evaluate evidence relevant to their beliefs can provide a conceptual framework for a consideration of how they do *in fact* evaluate it. Fischhoff & Beyth-Marom (1983) argue that Bayesian inference provides a general framework for evaluating hypotheses (beliefs) and that it is possible to describe a person's consistency with, or departures from, the theoretical model. They identify a set of logically possible deviations from Bayesian behaviour and review the research literature to see whether these possibilities correspond to observed behaviour in the normal population. It is argued below that this approach may usefully be applied to understanding the cognitive distortions shown by patients regarded as deluded.

A Bayesian Analysis of Delusional Beliefs

From a Bayesian perspective, knowledge is represented in terms of statements or hypotheses, H_i , each

of which is characterized by a subjective probability, $P(H_i)$, representing one's confidence in its truth. Bayes's theorem then governs the way in which the strength of one's belief in a hypothesis should be revised in the light of new information or data (D). In its simplest form, the theorem deals with the implications of the datum (D) for the relative likelihoods of a hypothesis (H) and its complement ($\bar{H}$). In such cases Bayes's theorem states that:

$$\frac{P(H/D)}{P(\bar{H}/D)} = \frac{P(D/H)}{P(D/\bar{H})} \cdot \frac{P(H)}{P(\bar{H})}$$

Reading from right to left, the three terms in the formula are: (i) the *prior odds* that H, and not $\bar{H}$, is true in the light of all that is known before the receipt of D; (ii) the *likelihood ratio*, representing the information value of D with respect to the truth of H; (iii) the *posterior odds* that H is true in the light of all that is known after the receipt of D. This approach has the advantage, for our purposes, of incorporating the level of prior belief explicitly in the inferential process. Fischhoff and Beyth-Marom point out that Bayesian inference is a normative scheme and that it is logically possible to deviate from optimal Bayesian performance in a number of ways. This provides us with a scheme for categorising different types of judgemental processes and considering whether a particular form of deviation is characteristic of a given group of people (e.g. deluded subjects). In the clinical setting, a consideration of the precise nature of the abnormal judgemental processes may have implications for attempts at modification of abnormal beliefs, such as those reported by Milton *et al* (1978).

Fischhoff & Beyth-Marom suggest a number of potential biases that can occur in hypothesis evaluation. These may occur at the stages of (a) hypothesis formulation (b) assessing component probabilities (c) assessing prior odds (d) assessing the likelihood ratio (e) "aggregation" (f) information search, or (g) action. For a given belief (hypothesis), a deluded subject may demonstrate deviation from the Bayesian model at one or more of the above stages.

(a) Hypothesis formulation

Fischhoff & Beyth-Marom indicate two possible sources of difficulty relevant to our discussion: failure to formulate a hypothesis at all, or formulation of an untestable hypothesis. They argue that for normal subjects the failure to formulate hypotheses is rare, but this may not apply to the transient beliefs of those traditionally described as hebephrenic schizophrenics: such patients appear at times to translate

abnormal experiences directly into belief statements, with no intervening stage of considering evidence which might be relevant to the related hypothesis.

Patients whose beliefs involve untestable hypotheses are frequently encountered in clinical practice. Perhaps the most common of such beliefs are those concerning knowledge of future events, e.g. the certain belief that the world will end in the year 2093 A.D.

(b) *Assessing component probabilities*

Beliefs must be translated into subjective probabilities, and the assessment of component probabilities is the second stage at which deviations from the model may occur. One such deviation would be the violation of the probability axioms, for example $PH + PH = 1$. Thus a subject might express 100% confidence that the IRA were plotting against him, but also a one-in-five chance that no such plot existed. Alternatively, poor assessment of component probabilities may result from miscalibration, i.e. the failure of one's confidence to correspond to reality. This might be viewed as an essential characteristic of delusional beliefs: however, normal subjects are frequently over-confident in their probability estimates (Lichtenstein *et al* 1982), even to the extent of frequent expression of absolute certainty (Fischhoff *et al*, 1977). The special peculiarity of deluded subjects is not the absolute certainty which is often apparent but rather the improbability of the events about which they express such beliefs.

A further well-known form of deviation at this stage is an over-reliance on the availability and representativeness of the data used as a guide to probability estimation (Kahneman *et al*, 1982). Subjects judge an event as likely to the extent that exemplars are easy to recall or imagine, and thus unusually salient events may be judged to be more frequent than is actually the case. This process appeared to occur in a young paranoid patient treated by one of the authors. He was preoccupied with his appearance and as a result felt that 80% of the people in the street were laughing at him. Accompanying him for a walk and counting those people who were smiling, not necessarily at him, produced a score (agreed with the therapist) of about 15%.

(c) *Assessing prior odds*

The assessment of prior odds represents the calculation of the ratio of the probabilities of competing hypotheses. Difficulties at this stage are largely

dependent on the earlier stages of hypothesis formulation and assessment of component probabilities. However, there are problems specific to this stage, e.g. the neglect of one of the hypotheses. When a person acts as though a hypothesis that is probably true is absolutely true, they have effectively neglected its complement. This aberration appears to be relevant in the case of certain delusions where the question of the probability of $\bar{H}$ is totally ignored: deluded patients frequently tell interviewers that they have never considered the possibility of the falsity of their beliefs.

(d) *Assessing the likelihood ratio*

This involves consideration of the information value of a datum with respect to H and $\bar{H}$. One possible error here, failure to consider $P(D/\bar{H})$, appears to be common in deluded patients. For example, one patient took the appearance of a police car in a busy thoroughfare as unequivocal evidence that the police were chasing him, neglecting the probability of this event occurring if the police had no interest in him. Similarly, the patient described above who erroneously estimated the probability of people smiling in the street had failed to consider alternative possible reasons for their behaviour.

It is also at this stage that the interaction of prior beliefs with new information occurs (Alloy & Tabachnik, 1984). Fischhoff & Beyth-Marom note that "the interpretation of new evidence may be affected by previous beliefs, thereby subverting the independence of the likelihood ratio and priors" (p. 247). Thus people can interpret and reinterpret new information so as to render it consistent with their beliefs. This type of error represents a less severe deviation from the normative model than does total failure to consider an alternative hypothesis: when such reinterpretation is encountered in deluded subjects, particularly if they acknowledge that the new (apparently inconsistent) data must be considered seriously, it seems that the abnormal belief system may be less resistant to change (Brett-Jones, 1984).

(e) *Aggregation errors*

Although Fischhoff & Beyth-Marom describe the possibility of an error at the aggregation stage of the model, i.e. in the computation of the product of prior odds and likelihood ratio, they present no common examples of such an error. Nor is it clear what role such an error might play in the maintenance of abnormal beliefs.

(f) Information search

Information search, the sixth stage, does appear relevant to our enquiry. Some deluded subjects report no information search relevant to their belief at all. For example, one patient had experienced a "delusional perception" at the stage of formation of his belief. A "delusional perception" is a primary disturbance of symbolic meaning, with no disturbance of perception, sensation or thinking. The basic feature is "the establishment of an unfounded reference" (Gruhle, 1915). The belief was that he was in direct contact with, and could influence, a famous athlete. He described how he had no need for any confirming or disconfirming evidence, so certain had the initial experience rendered him. In the authors' experience, many deluded subjects fail to search for information relevant to their hypotheses, since their conviction renders this, in their eyes, unnecessary. Other patients do search for information, but restrict the search to confirmatory evidence.

(g) Action

Action is the seventh and final stage of the Bayesian model. The output of the process of Bayesian inference, i.e. the posterior odds, summarises the subject's beliefs in a way that facilitates selecting the optimum course of action. However, it is clear that the relationship between belief and action is far from simple, even for normal subjects. Fischhoff and Beyth-Marom note that "believing H" is not equivalent to acting as though H is true, and suggest that we may in general be more cautious in our actions than in our expressions of belief. There is a considerable literature on the subject of an individual's willingness to stake money on his/her beliefs, and generally it is found that subjects are indeed more cautious in their actions than in their statements (Fischhoff *et al.*, 1977). With deluded subjects, one frequently striking feature is their remarkable lack of action congruent with apparently sincerely held beliefs.

Non-Bayesian Considerations

A number of other points, not covered by Bayesian analysis, are worthy of consideration here, before discussing experimental approaches suggested by the theoretical models. These concern the role of hallucinations in the formation and maintenance of delusions, and the question of generalised distortion *vs* content-specific or mood-specific distortion or processing.

The role of hallucinations

Hallucinations often appear to play a special role in the formation and/or maintenance of delusions. At the stage of hypothesis formation, hallucinations are data, often distressing and uncontrollable, for which an explanation must be found. Most individuals infer, understandably, that their experiences are the result of the activities of real objects or beings; and when, for example, the source of an auditory experience cannot be detected by the other senses, infer the existence of some other source for the sounds. Thus far, the processes appear "normal", although the resultant hypothesis may be fantastical. What appears to be abnormal is extent to which the belief is then maintained in the face of social rejection of its truth and the provision of an alternative hypothesis—that the individual is ill. Is it the special salience of the data—its ego-involving content and striking, often persistent, availability—which enables the formation and maintenance of this idiosyncratic explanation?

Content specificity

Is the distortion of processing in the deluded individual a generalised distortion of all judgemental processes, is it content-specific, or is it mood-specific? Cognitive deficits have been widely studied—e.g. in schizophrenia—but there has been relatively little attention paid to this particular question.

Winters & Neale (1983), in a review of theories of delusions, describe a number of "deficit" models, which invoke some dysfunction of cognitive processing (such as deficits in perceptual processing) to account for the formation of a delusional belief. However, the precise roles of specific cognitive deficits in the formation of delusions have not been experimentally identified or tested.

Arieti (1974) proposed that schizophrenic individuals form delusions through a failure of syllogistic reasoning, which is more generalised across content in some diagnostic sub-groups than in others. However, an experimental study of this hypothesis reported by Chapman & Chapman (1973) produced inconclusive results, and current reviewers such as Winters & Neale (1983) find little support for this view.

Robertson & Taylor (1985), in a study of 61 convicted schizophrenics and 41 "normal" prisoners, found that on tests of cognitive functioning the "deluded" sub-group of schizophrenics were closer to the "normals" than were the "mixed symptom" sub-group or the "simple schizophrenic" sub-group. However, the "deluded" group performed poorly

on two tasks of "what might be called immediate memory" (p. 95). The authors speculated that it may be that such people are liable to misinterpret external stimuli. This hypothesis is of the "deficit" type and implies a generalised distortion of judgemental processes.

Brennan & Hemsley (1984) on the other hand, in a study of illusory correlations (i.e. reported correlations of two events which in reality are not correlated) found a content-specific effect. On a task which involved stimuli particularly relevant to patients with paranoid delusions, a paranoid schizophrenic group reported particularly strong illusory correlations compared with a non-paranoid schizophrenic group and a "normal" group. A fuller investigation of the content-specificity of deluded subjects' distorted processing is overdue. Within experimental psychology, information-processing studies have recently been criticised for neglecting the role of content in tasks (Claxton, 1980) and for an over-reliance on neutral material.

Mood specificity

Although there is considerable literature concerning cognitive processing in depression, little if any experimental work has been published which involves *deluded* depressed patients. Do deluded depressed or manic patients exhibit generalised distortions of processing of material unrelated to their mood state? Can distortions of processing be detected in asymptomatic patients?

It is reasonable to speculate that these distortions are mood-specific: in depressed or euphoric states, the individual may be guided more by affective than by cognitive processing (Zajonc, 1980; Bower, 1981). Such is its salience that the experience of the mood state may take precedence over other types of data ("I feel (very strongly) like this, therefore I am this"), or may in some way influence inferences and information search: thus the manic patient, feeling excited, requires no further evidence to support his identification of his current feelings with an existential view, and may come to hold a grandiose self-perception regardless of other data. This hypothesis bears some similarity to Maher & Ross's (1984) view of delusions as explanations of anomalous experiences.

Experimental Approaches

This review of the literature suggests a number of experiments to clarify the processes of formation and maintenance of delusions. To test for generalised

or content-specific "distortion", it is possible to compare deluded and control subjects' performance on a "neutral" task of hypothesis formation. Volans (1976) reported an experiment involving the formation of hypotheses about the probability of a coloured ball being drawn from one of two hidden bags containing different proportions of two sets of coloured balls. This experiment allows for an examination of (i) the strength of the initial hypothesis, (ii) the number of trials taken to reach certainty, and (iii) the role of confirming and disconfirming evidence. Obsessional subjects were found by Volans to differ from controls on this task: it remains to be seen whether deluded subjects would differ in judgemental style, and thus show evidence of generalised distortion.

Given a Bayesian analysis, it is possible to devise experiments to test for deviations from the normative model; and a wealth of carefully designed experiments, used with normal subjects by Fischhoff and colleagues, is already available. In interpreting the results of any such experiment, however, "normal" deviation from the prescriptive model must not be forgotten: deluded subjects must be shown to differ quantitatively or qualitatively from "normal" controls, rather than simply deviating from the model itself, if claims of abnormality are to be justified.

Conclusions

The clinical relevance of the experimental approaches suggested resides in their potential for improving both the system of classification and the methods of modification of delusions. This systematic form of assessment of delusions (involving consideration of judgemental processes, content and mood) might aid the valid identification of subgroups predictive of such factors as change and aetiology. For those delusions untreated by current methods, a careful individual analysis of the reasoning process might identify the point in the process at which attempts at modification might be most effectively. (The patient described above, who was concerned about people smiling at him, was helped by treatment which successfully focused on a re-assessment of the frequency of people smiling in the street). Rachman (1983) describes a number of ways in which the findings of this branch of cognitive psychology may further our understanding of and therapy for abnormal beliefs.

In this paper, we have attempted to draw attention to current work in the field of normal psychology which has relevance to the study of delusions. This work has implications for certain basic questions

concerning the nature of the deluded individual's dysfunction, and points to new approaches in assessment of individual cases and the experimental analysis of delusions. Such approaches, it is hoped, will open the way to new possibilities in the psychological treatment of deluded individuals.

Abnormal Illness Behaviour and Anxiety in Acute Non-Organic Abdominal Pain

P. R. JOYCE, J. A. BUSHNELL, J. W. B. WALSH and J. B. MORTON

Of 105 patients admitted to a surgical ward with acute abdominal pain, 18 were considered to be without evidence of any organic aetiology for this symptom. These 'non-organic' patients were almost all female and differed from the 'organic' patients in state anxiety and in the illness behaviour questionnaire scales of psychological versus somatic perception, denial and affective disturbance. The two groups of patients could be differentiated on the basis of scores derived from the Illness Behaviour Questionnaire, and the State-Trait Anxiety Inventory.

In a considerable proportion of patients admitted acutely to a surgical ward with abdominal pain, no specific organic pathology is found. Some patients are observed and discharged while others undergo various medical or surgical procedures, most commonly appendicectomy. Various studies show that in 10-30% of patients undergoing this operation, no organic pathology is found (Jess *et al*, 1981; Boerema *et al*, 1981; Chang, 1981). Young women appear to be especially at risk of having a normal appendix removed (Lee, 1961). Comparison of life events and psychiatric disorder in patients complaining of abdominal pain, with and without histologically confirmed appendicitis, found an excess of both psychiatric symptoms (mainly depression) and of adverse life events in those whose appendix was not acutely inflamed. Creed (1981) suggested, as have others (Ingram *et al*, 1965; Meyer *et al*, 1964), that psychosocial factors are major contributors to the problem of appendicectomy in which the appendix is not acutely inflamed.

We hypothesised that depression, anxiety or some form of abnormal illness behaviour were the likely psychiatric reasons for admission to hospital with acute abdominal pain when no organic pathology was found. We thus set out to determine whether patients without an organic basis for their abdominal pain would differ from those with an organic basis for their pain on measures of depression, anxiety and abnormal illness behaviour.

Method

On the day following admission to a surgical ward at Christchurch Hospital, all patients with a major presenting complaint of abdominal pain between ages 15 and 60 years were approached and asked to participate in this study.

If patients agreed they were asked to complete the State-Trait Anxiety Inventory (STAI) (Spielberger *et al*, 1969), the Zung Self-rating Depression Scale (SDS) (Zung, 1965), and Pilowsky's Illness Behaviour Questionnaire (IBQ; Pilowsky *et al*, 1979).

After a minimum of six months (time to allow for any possible review of diagnosis) and without reference to the psychological test scores, the surgical notes were reviewed and the diagnosis recorded. If this was appendicitis, it was checked that it had been histologically confirmed. If non-specific abdominal pain was the diagnosis, then the notes were searched for any evidence of physical abnormalities such as an elevated temperature, white blood count or erythrocyte sedimentation rate, which suggested an organic aetiology.

Patients were grouped into four diagnostic categories: those with appendicitis, those with other organic diagnoses, those with non-specific abdominal pain with physical abnormalities, and those with non-specific abdominal pain without physical abnormalities. The mean (and standard deviation) for trait anxiety (range 20-80), state anxiety (range 20-80), Zung depression (range 20-80), and the seven scale scores of the IBQ were calculated for each diagnostic grouping. Categorical data were compared using a chi square test, while continuous variables were compared using Student's *t*-test. Using the data for female patients only, a stepwise discriminant analysis (SPSS-II) was performed on the 40 questions in the IBQ which contribute to its seven scales.

Results

During the course of this study 121 patients were admitted acutely to surgical wards with abdominal pain. Twelve were not approached (poor comprehension of English, staff members or too sick) and four declined to participate after having seen the questionnaires. The remaining 105 patients are the subjects of this study, and the most common surgical diagnoses were: appendicitis ($n=33$), non-specific abdominal pain (37), of whom 19 had and 18 did not have

abnormal physical findings, gastric-duodenal ulceration (5), gastroenteritis (4), pancreatitis (3), diverticular disease (3), cholelithiasis-cholecystitis (3), and 15 other diagnoses for either one or two patients. The duration of pain for these patients was skewedly distributed, with 82% having had their pain for less than seven days, although five reported pain for more than 99 days.

Table I presents the data (mean $\pm$ standard deviation) for all patients, by diagnosis. As the appendicitis, other organic cause and non-specific abdominal pain with physical abnormalities groups did not differ on any psychological variable, and to simplify statistical comparison, they are combined into one 'organic' group. This combined 'organic' group differs from the 'non-organic' group (i.e. non-specific abdominal pain without physical abnormalities) in terms of sex ratio, state anxiety, and on three scales of the IBQ (somatic versus psychological perception, affective disturbance and denial).

Although males and females with an 'organic' abdominal pain did not differ significantly on any of the seven scales of the IBQ, the illness behaviour discriminant analysis was performed on the data from females only, with the aim of examining differences between those with an 'organic' from those with a 'non-organic' abdominal pain. Table II lists the 12 items from the IBQ which were found to contribute to the illness behaviour discriminant score.

While the 'non-organic' patients had a significantly higher state anxiety, a better discrimination for individual patients was obtained using the state-trait anxiety difference. Using the maximally discriminating cut-off (state-trait difference ≥ 12), then 10/17 female 'non-organic' patients and 6/44 female 'organic' patients ($\chi^2 = 12.7, P < 0.001$) had this considerably higher state than trait anxiety. (Among the 'organic' males, 5/43 had a similar high state trait difference.) In Figure 1 the state-trait anxiety difference is plotted against the illness behaviour discriminant scores for 'organic' and 'non-organic' female patients.

In order to search for heterogeneity among patients who had 'non-organic' abdominal pain, the subjects were divided into those who confirmed and those who denied having had the same pain before (Table III). Those who had never had the same pain before had a higher state-trait anxiety difference but tended to have a less abnormal illness behaviour discriminant score (especially note the IBQ scale of psychological versus somatic perception).

Discussion

Within this group of 105 patients admitted acutely with abdominal pain, the most common surgical diagnosis was non-specific abdominal pain, closely

followed by appendicitis. However, those patients with non-specific abdominal pain could be divided into two groups. One group included both sexes and had abnormal physical findings; psychologically, these patients did not differ from other patients with an 'organic' cause for their abdominal pain. The second was predominantly female, did not have any abnormal physical findings, and these patients reported more state anxiety and achieved more abnormal scores on various measures of illness behaviour. Without taking into account the distinction between the presence, or absence of abnormal physical findings, the abnormal psychological findings would be partially masked. It seems reasonable to assume that all the patients with non-specific abdominal pain were regarded and treated similarly by the surgical teams, thus making it unlikely that the abnormal psychological findings arose in one group but not the other while the patients were in hospital.

Pilowsky (1978) developed the concept of abnormal illness behaviour and showed that pain clinic patients could be discriminated from general practice patients using a discriminant function which utilised the IBQ scales of psychological versus somatic perception, disease conviction, denial and irritability (Pilowsky *et al.*, 1979). Demjen & Bakal (1981) found that in patients with chronic headaches, those with continuous pain differed from those with episodic pain in their illness behaviour on the scales of psychological versus somatic perception and of denial. In the present study the non-organic patients differed on the scales of psychological versus somatic perception, denial and affective disturbance. In all three studies the IBQ scale of psychological versus somatic perception showed the greatest difference between groups.

Examination of the 12 questions which contribute to the illness behaviour discriminant score suggests a caricature of the female 'non-organic' abdominal pain patient as one whose health is the greatest difficulty of her life, who fears she may suddenly fall ill, who denies having silly thoughts about health yet thinks there is something seriously wrong with her body, who admits to no problems or personal worries other than her illness, and for whom illness may be construed as a punishment. These patients also deny feeling irritable towards other people and yet lose patience with them, while being unable to express angry feelings. These characteristics have been described by many earlier writers on pain-prone patients (e.g. Engel, 1959; DeVaul & Faillace, 1978; Blumer & Heilbronn, 1981).

Although the patients with 'non-organic' abdominal pain differed in terms of state anxiety from the

'organic' patients, they did not differ in terms of trait anxiety or depression. This latter finding is inconsistent with that of Creed (1981), who emphasised depression. Perhaps this discrepancy arises from methodological differences, in that we measured depressive symptoms (by self-report questionnaire), while Creed assessed for the presence of a depressive syndrome on the basis of a mental state examination.

When attempting to discriminate between the 'non-organic' and 'organic' patients on affective measures, the best separation of individuals is achieved not by state anxiety alone, but by the state-trait anxiety difference. We are not aware that this measure has previously been used, but it appears to have face validity in that it represents the difference (on very similar questions) between how a patient is at the present moment and how he or she generally is. This is possibly a measure of acute anxiety or exacerbation of anxiety.

The state-trait anxiety difference is not only of interest in discriminating between patients with 'organic' and 'non-organic' abdominal pain, but also when the 'non-organic' patients are divided into those who have and those who have not had a similar pain before. This division suggests the possibility of two subgroups: those subjects who have never had the same pain before tend to be younger, have a normal trait anxiety but a marked state-trait anxiety difference, and score less abnormally on the IBQ, especially on the somatic versus psychological perception scale. The other subgroup who have had the same pain before, tend to be older, have a less marked state-trait anxiety difference but a higher trait anxiety and score more abnormally on the IBQ, especially on the somatic versus psychological perception scale. Although the illness behaviour variables and anxiety variables are not totally independent, this division suggests a subgroup with acute pain related to acute anxiety, and one with recurrent pain associated with chronic anxiety and abnormal illness behaviour.

As the number of 'non-organic' patients is relatively small, and even this group may be heterogeneous, and because we have not repeated this derived discriminant function on a second sample, we are reluctant to explore issues such as sensitivity, specificity and hit rate on these data. However, the discrimination obtained between 'organic' and 'non-organic' patients (Figure 1) is remarkable, and supports the hypothesis that psychological factors are of relevance in those patients with acute abdominal pain in whom no 'organic' pathology is found.

Although there are limitations to dividing dis-

orders into those with and without an 'organic' aetiology, especially in view of the dependence of the emotions upon a physiological substrate, this dichotomy is likely to remain useful while surgeons and other medical staff have to make decisions about whether or not to treat. Our results emphasise the psychological differences between these groups of patients. Even when it is acknowledged that the pain of a patient without an organic aetiology is no less real, and the patient is in no less need of assistance for that distress, seeking medical attention and

treatment for pain may decrease the likelihood that an appropriate therapeutic response to the patient's psychological distress will occur. An inappropriate treatment response may then help to perpetuate a pattern of abnormal illness behaviour.

Acknowledgements

We thank Penny Brander for assistance with statistical analysis of the data and the surgeons at Christchurch Hospital who allowed us to interview their patients and the patients for their cooperation.

(Accepted 15 January 1985)

The SOMA—A Questionnaire Measure of Sexual Anxiety*

D. G. PATTERSON and E. C. O'GORMAN

SOMA, a questionnaire designed by J. T. Quinn to measure sexual anxiety in patients presenting at a psychosexual clinic, has been used extensively as a clinical and research tool. Its construction and scoring are described, and data are presented for internal consistency, test-retest reliability, principal components analysis, and validity. Practical applications for diagnosis, prognosis, and research are discussed.

Anxiety and sexual dysfunction have long been associated with one another; psychoanalytical theory, learning theory, and the theories underlying sex therapy have all emphasised anxiety as an aetiological factor (Kaplan, 1982). Various methods of treatment of sexual dysfunction emphasise the relief of anxiety. Psychoanalysis holds that the resolution of deep-seated conflicts may relieve anxiety, while learning theories concentrate on specific circumstances that evoke and maintain disturbed behaviour in the current situation. Masters and Johnson (1970) described methods to alleviate 'performance anxiety', while Kaplan (1974), (1982) has discussed the use of psychodynamic techniques, sexual and communication tasks and tricyclic antidepressants to alleviate anxiety. Anxiety in the form of heterophobia is also considered to play a part in the genesis of homosexuality, and various treatment methods have been shown to be effective in changing sexual orientation; these include aversion relief (Thorpe *et al*, 1964) and desensitisation (Kraft, 1967).

Despite the emphasis given to sexual anxiety in the literature, few attempts have been made to devise instruments to measure it (see Norton & Jehu (1984) for a review of work in this field). Earlier research workers tended to use non-standardised methods of self-reporting of anxiety in certain sexual situations. Another approach has been the measurement of generalised neurotic anxiety in subjects with sexual dysfunction, but Cooper (1968) suggested that anxiety specifically related to sexual activities may be more important than general anxiety in the aetiology of sexual dysfunction. Hatch (1981) described psychophysiological measures of anxiety in patients with sexual dysfunction, which is an interesting

approach worth further research. Janda & O'Grady (1980) have described the development of the Sex Anxiety Inventory, consisting of 25 items with a forced-choice format; one of the responses to each item indicates sexual anxiety. The scoring system awards one point for each item on which the subject selects the response associated with anxiety. One disadvantage of such a system is that no allowance is made for the degree of anxiety experienced, so that a subject who feels only mildly anxious on a large number of items will be rated as highly anxious, whereas one who is extremely anxious about a small number of items will be rated as having only a mild degree of anxiety. Two further inventories are the Derogatis Sexual Functioning Inventory (Derogatis & Meyer, 1979) and the Sexual Arousal Inventory (Hoon *et al*, 1976) both of which purport to measure coital anxiety. Although inventories examine a comprehensive range of sexual skills and situations this unfortunately involves a loss of specificity.

It seemed valuable from a clinical standpoint to be able to measure the degree of sexual anxiety in patients presenting at a sexual dysfunction clinic. If such a measure were available, treatment could be more effectively planned for example, a high degree of heterosexual anxiety might indicate that particular attention should be paid to the desensitisation elements in the programme, or to counselling with a view to anxiety relief. SOMA (Sexual Orientation Method and Anxiety) is a questionnaire designed to measure sexual anxiety. It consists of items from the Sexual Orientation Method (Feldman *et al*, 1966), interspersed with questions relating to sexual anxiety, for which the scales were extracted from the semantic differential (Marks & Sartorius, 1968).

*The complete questionnaire and score sheet are available from The Secretary, Department of Mental Health, The Queen's University, 68 Fitzwilliam Street, Belfast BT9 7AB. Enclose the sum of £1 on application.

Mean pretreatment and post-treatment heterosexual anxiety scores

Clinical response	Pretreatment	Post-treatment	Pre-treatment inconsistencies
Improved (<i>n</i> = 17)	7.1 ¹	5.2	0.8
No change (<i>n</i> = 18)	7.2 ²	6.9	0.8
Worse (<i>n</i> = 11)	6.5 ²	6.7	1.8

¹*P* ≤ 0.001 (Wilcoxon Test)

²Standard deviation not significant.

sexual anxiety, 77% of subjects had 0 or 1 inconsistencies and 94% had two inconsistencies or less. For homosexual anxiety, 63% of subjects had 0 or 1 inconsistencies and 94% had less than three inconsistencies. This suggests that the technique gives a high degree of internal consistency of responses.

McCafferty (1984) studied a questionnaire of similar construction to SOMA in subjects with sexual dysfunction. He showed that subjects who had a high number of internal inconsistencies in their pretreatment testing had a poorer outcome after treatment than did those with a low number of inconsistencies. This phenomenon may reflect a personality trait or lack of commitment to treatment.

Forty-six subjects took part in an outcome study. They were assigned to one of three outcome groups: 'clinically improved', 'no change' and 'clinically worse'. All subjects completed SOMA prior to treatment; the means of the inconsistencies for the heterosexual anxiety scale for each of the outcome groups, is shown in Table II. The mean for the group who were 'clinically worse' after three months of treatment is higher than the means of the other two groups; this difference is statistically significant (*P* < 0.001, Mann-Whitney), suggesting that a high inconsistency score at initial testing may be a prognostic indicator of poor outcome.

Test-retest reliability was studied in patients who completed SOMA at their initial attendance but for some reason did not commence therapy immediately. If the delay was longer than eight weeks, the patient would normally be asked to complete the questionnaire again. These two administrations were considered as test and retest occasions: no treatment was received between test and retest. The patients had a variety of diagnoses.

The heterosexual anxiety and homosexual anxiety scores at the test and retest occasions were recorded for 35 subjects. Spearman rank correlation for the heterosexual anxiety scores was +0.95 (*P* < 0.001); for homosexual anxiety the correlation was lower (+0.75, *P* < 0.001) with a tendency for increased scores on retesting.

A principal component analysis was performed on the data obtained from 228 patients who attended a psychosexual clinic. A varimax rotation was then applied; the

matrix is shown in Table III. Three factors are extracted, which account for 93% of the total variance in the scores. The first may be seen as an 'orientation' factor involving the heterosexual and homosexual scores; the second is a 'dysfunctional' factor involving the heterosexual anxiety and homosexual scores, and the third factor is one of homosexual anxiety. All four scores contribute usefully to the information obtained. It would be possible to reduce the final amount of data presented to three items, i.e. the numerical scores on each factor. However, it has been kept in its original form in the interests of simplicity.

TABLE III
Varimax rotated factor matrix

Scores	Factor 1	Factor 2	Factor 3
Heterosexual	-0.70	-0.62	-0.02
Homosexual	0.89	0.13	0.35
Heterosexual anxiety	0.08	0.95	-0.17
Homosexual anxiety	-0.22	-0.14	0.95
Percentage of variance accounted for	55	22.4	15.7

Validity

Validation of SOMA was approached in two ways. The first involved the study of groups of subjects with assumed increased heterosexual anxiety. Two groups of normal subjects were drawn from hospital staff and medical student volunteers. These groups were unselected, except that they were of an age to be potentially sexually functioning, claimed to be heterosexual in orientation, and were satisfied with their orientation. There were 27 'normal male' subjects

TABLE IV
Means and standard deviations of scores (standard deviations are given in brackets)

	<i>n</i>	Heterosexual score	Homosexual score	Heterosexual anxiety	Homosexual anxiety
Normal males	27	45.70 (2.45)	12.63 (6.04)	3.93 (3.15)	9.96 (3.48)
Dysfunctional males	46	41.50 ¹ (6.38)	9.28 (5.20)	6.26 ¹ (4.48)	9.61 (3.34)
Homosexual males	62	25.53 ³ (10.53)	39.58 ³ (7.93)	8.23 ³ (3.90)	7.00 ³ (4.50)
Normal females	20	41.75 (4.20)	12.18 (2.35)	4.30 (3.07)	9.08 (4.98)
Dysfunctional females	52	30.90 ³ (12.41)	12.10 (8.21)	8.10 ² (3.94)	10.24 (3.55)

Levels of significance compared with normal subjects using the Mann-Whitney U-Test. ¹ $P \leq 0.05$; ² $P \leq 0.01$; ³ $P \leq 0.001$.

and 20 'normal female' subjects. Their scores are shown in Table IV.

Three groups of patients attending a psychosexual clinic were assumed to have increased heterosexual anxiety; these were dysfunctional males, dysfunctional females, and homosexual males. The dysfunctional groups included all patients presenting with any form of sexual dysfunction at the clinic in 1980 or 1981; in the case of dysfunctional males, this included erectile and ejaculatory dysfunction as well as disorders of arousal. The group of dysfunctional females similarly included disorders of arousal and orgasmic dysfunction. These scores were compared with those of normal subjects of the same sex. As predicted, these groups have higher scores on the heterosexual anxiety component of the SOMA than the non-clinical groups (Table IV).

The second approach to validation was to compare pre-treatment and post-treatment scores; it might be postulated that high pretreatment levels of sexual anxiety would tend to fall during treatment. Fifty patients who presented with sexual dysfunction were included in an outcome study; both sexes were represented and each patient completed the SOMA at the second pretreatment attendance at the clinic. At the same attendance, each patient was assessed clinically by one of the authors. Three months later each post-treatment subject was asked to complete the questionnaire again, and was again assessed clinically by the same author who was blind to the results obtained by the subjects on the SOMA on either occasion. Clinically, each patient was rated on a three-point scale as either improved, no change, or worse. Patients were also asked to class themselves subjectively as improved, the same, or worse. Those patients who both reported improvement and were rated as improved by the clinician were assigned to the 'improved' group. All were still undergoing therapy at the time of post-treatment assessment. Patients were graded as 'worse' if they either gave self-rating as worse or were rated by the clinician as worse. Five of these eleven patients had

failed to continue attendance at the clinic; they were rated by the clinician and completed SOMA at their homes. Four patients who could not be interviewed were dropped from the study; the remaining 18 (8 of whom had dropped out of treatment) were assigned to the 'no change' group.

The means and standard deviations for heterosexual anxiety for each of the three groups on the two test occasions are given in Table II, which shows a significant change in the expected direction for the improved group.

In order to further examine the nature of the homosexual anxiety and heterosexual anxiety scales, 52 subjects were asked to complete three additional questionnaires:

- The Hostility and Direction of Hostility Questionnaire (Caine *et al.*, 1967). This assesses a wide range of manifestations of aggression, hostility, and punitiveness. In this study, the questionnaire was used to assess intropunitive hostility and extra-punitive hostility, and to examine their relationship with sexual anxiety, as measured by SOMA.
- The Eysenck Personality Questionnaire (Eysenck & Eysenck, 1975). The relationship between sexual anxiety and the neuroticism, extraversion and psychoticism scales of this questionnaire were examined.
- The Taylor Manifest Anxiety Scale (Taylor, 1953). The relationship of sexual anxiety to the measures of manifest anxiety and defensiveness were examined.

For the purpose of this comparison, all 52 subjects were chosen from the group of dysfunctional females; spurious correlations might otherwise emerge between different diagnostic groups. Spearman rank correlations were calculated for all these questionnaire scales and the heterosexual anxiety and homosexual anxiety scales of the SOMA. None of the correlations were significant. Thus sexual anxiety as measured by the SOMA is not merely a reflection of general anxiety.

Discussion

SOMA is a valid and reliable questionnaire which measures sexual anxiety in patients presenting with sexual problems. It is a useful diagnostic tool, when interpreted in the light of the normal clinical interview, but is not designed to assess sexual anxiety in subjects not presenting with sexual problems. As it indicates those patients with marked heterosexual anxiety, it should be of value in helping therapists to select those in whom treatment for anxiety will be of importance. It may also act as a prognostic indicator, in that those patients with high levels of sexual anxiety are likely to respond best to current forms of therapy. It is noteworthy that some patients present with

sexual dysfunction in the absence of marked sexual anxiety; this suggests that the current theoretical models concerning the origins of sexual dysfunction may be incomplete.

SOMA should be of value in clinical research into types of sexual anxiety and their distribution in the population. For this purpose the test requires a wider standardisation on non-clinical subjects, selected in terms of age, social status, and sexual experience. We have demonstrated that SOMA is sensitive to clinical improvement, and should thus be of value in research into the outcome of treatment. Serial testing on clinically improving subjects may give greater insights into the nature of clinical improvement.

Psychiatric Disorders in Mildly and Severely Mentally Retarded Urban Children and Adolescents: Epidemiological Aspects

C. GILLBERG, E. PERSSON, M. GRUFMAN and U. THEMNER

A total of 149 children aged 13-17 years were examined. 83 were mildly and 66 severely mentally retarded. These children, especially the severely retarded ones, are representative of all mentally retarded children born in 1966-1970 and living in Göteborg, Sweden. 64% of the severely mentally retarded and 57% of the mildly mentally retarded children were suffering from a handicapping psychiatric condition. Autism-like 'psychotic behaviour' was common in the severely retarded. 0.2% of the total child population aged 13-17 years suffering from the combination of mental retardation and 'psychotic behaviour'. Epilepsy was associated with psychiatric abnormality, but Down's syndrome was generally not so associated.

Epidemiological studies of psychiatric disorders in mentally retarded children are scanty. Rutter *et al* (1970) performed a comprehensive study on the Isle of Wight in the 1960s and found the prevalence of behaviour problems—severe and mild—in children with mental retardation to be three or four times more common than in randomly selected children of a corresponding age-group. This is probably the only previous population-based study of psychiatric disorder in intellectually retarded children, and the findings are in need of corroboration. It is now almost 20 years old, was carried out in a typically rural area, and its total number of severely retarded children was small ($n=38$). Modern studies, especially from urban areas where psychiatric disorders are known to be more frequent than in rural settings, might well yield higher prevalence figures.

The present study, derived from a population-based series of 164 Swedish urban children with IQ < 70 and born in the period 1966-1970, had the following aims: to establish prevalence figures for psychiatric disorder in mentally retarded children and adolescents; to analyse the particular kind of psychiatric disorder in individual children; to analyse the effect of the degree of mental retardation on the occurrence and quality of psychiatric disorder; and to assess the association between psychiatric disorders and the additional impairments of epilepsy and Down's syndrome.

Method

Definition of terms

In accordance with the World Health Organisation recommendation of 1968, mild mental retardation (MMR)

was defined as an intellectual level in the tested IQ range of -3.3 to -2.0 standard deviation (SD) from the mean of 100 ($SD=15$), i.e. as an IQ of 50-70. The Wechsler Intelligence Scale for Children or the Terman-Merrill test were used. Severe mental retardation (SMR) was diagnosed in cases with IQ < 50.

All children showing a persistent (i.e. lasting longer than 1 month) psychiatric condition, handicapping to him or herself or to others, were diagnosed as suffering from a psychiatric disorder. Seven main psychiatric diagnostic categories were used:

- (a) *psychotic behaviour* (Gillberg, 1983), including cases with (i) infantile autism (DSM-III, 1980), (ii) schizophrenia (DSM-III, 1980), (iii) the triad of language and social impairment (Wing & Gould, 1979), excluding infantile autism and other classifiable childhood psychoses, (iv) severe impairments of social interactions, and (v) Asperger's syndrome (Wing, 1981)
- (b) *depressive syndrome*, as defined by Spitzer *et al* (1975)
- (c) *conduct disorder* in cases showing socially unacceptable behaviour, such as stealing, firesetting, or running away from home
- (d) *emotional disorder* in cases where anxiety and fear without loss of reality-sense were the most incapacitating symptoms
- (e) *psychosomatic disorder* in cases with abdominal pains, vomiting, diarrhoea, headache, and secondary enuresis or encopresis occurring in situations of psychic stress and without apparent physical cause
- (f) *hyperkinetic disorder* in cases with generalised hyperkinesia (i.e. hyperkinetic behaviour in several different settings)
- (g) *other psychiatric disorder* in cases which could not be included under any of the foregoing headings.

Some children were diagnosed according to more

TABLE I
Description of the mentally retarded series in the psychiatric follow-up study

	SMR	MMR
Number in original epidemiological study	73	91
Prevalence (%)	0.30	0.37
Dead at follow-up	4	0
Moved to another region	1	4
Refused to participate	2	4
Total attrition rate at psychiatric follow-up (dead excluded) (%)	3	8
Number in psychiatric follow-up study	66	83
Boy:girl ratio	38:28 (1.4:1)	54:29 (1.9:1)
Age range	13-17	13-17
Epilepsy: <i>n</i> (% in brackets)	18 (27)	8 (10)
Down's syndrome: <i>n</i> (% in brackets)	18 (27)	2 (2)

than one psychiatric diagnostic category. In such cases, a hierarchy was used in accordance with the order of listing given above. For example, if the child had been diagnosed as suffering from both an emotional disorder and a depressive syndrome, the latter was considered the main diagnosis.

All children on anti-epileptic medication because of 'epilepsy' or who had had at least one seizure in the 12 months preceding the psychiatric study were diagnosed as suffering from epilepsy.

Population investigated

The original population studied consisted of all children born in 1966-1970 living in Göteborg on the 31 December 1978—a total of 24 498 children. Gothenburg is an industrial city on the West Coast of Sweden with 450 000 inhabitants. Through screening and register searches (as described by Hagberg *et al.*; 1981a, 1981b) 91 children with MMR and 73 children with SMR were found, corresponding to population frequencies of 0.37% and 0.30% respectively. The prevalence figure for SMR is considered a true one, whereas that obtained for MMR is a minimum one. The MMR category did not comprise only cases known to services for handicapped children, since 20% were ascertained by screening procedures in schools. We believe that the majority of clearly mentally retarded children with IQ < 70 in the studied age-group have been detected.

The children were examined during the spring of 1984, when they were 13-17 years-old. Details of the series examined are given in Table I.

TABLE II
Psychiatric disorders in cases with severe mental retardation

Disorder	<i>n</i> (%)	% with epilepsy	% with Down's syndrome	Boy:girl ratio
So severely retarded that rating of psychiatric state was not possible	7 11	57	29	1.3:1
No psychiatric disorder	17 26	0	53	0.9:1

Total with psychiatric disorder	47 57	11	0	2.9:1

Psychiatric diagnostic assessment

All children were seen individually, and assessed by at least one of three doctors who all had a minimum of six months' training in child psychiatry. Each doctor examined approximately 50 of the 149 children. The first author is a child psychiatrist with special training in the field of mental retardation, childhood psychoses, and child neurology; he first examined between three and six children, each in collaboration with the second or third author, until agreement regarding symptoms and ratings of psychiatric disorders was reached. One of the parents (usually the mother) was interviewed with a highly structured manual covering psychiatric symptomatology, social and family factors, developmental milestones, siblings' and parents' health, hereditary factors, important somatic disorders, and treatment given by other doctors. The child was observed (and interviewed whenever appropriate) for at least 40 minutes. All manuals, medical records, and interview questionnaires were reviewed by the first author, and comprehensive diagnoses formulated by him; the complete diagnostic evaluation battery is available on request.

For statistical comparison, chi square tests with Yates' correction were used.

Results

Children with severe mental retardation

The results for this group are summarised in Table II. About one in ten of the SMR children were so severely mentally

handicapped, and hence their behavioural repertoire so limited, that it was impossible to make a psychiatric classification. Only about one quarter of the SMR children were considered clearly psychiatrically normal. Altogether, 64% of the group showed major psychiatric disorders. The disturbances grouped in the 'psychotic behaviour' category were by far the most common, affecting exactly half of all the SMR children, but only 15% of these children showed infantile autism; the remaining 85% were all severely psychiatrically disturbed, had problems in the fields of social relationships and language, and demonstrated deviant behaviour such as ritualism, resistance to change, self-destructiveness, and hyperactivity. More than half ($n=9$) this group with 'psychotic behaviour' were pervasively hyperactive, but because they all showed concomitant severe disturbances of social relatedness and language, they were not classified separately as suffering from 'hyperactive disorder'.

The calculated frequency for the combination of SMR plus 'psychotic behaviour' in the general population was 0.15% in the 13-17 year age-group.

All other psychiatric disorders were much less frequent in the SMR group, but it was possible to definitely diagnose disorders such as 'depressive syndrome' and 'conduct disorder' in a few children.

Children with mild mental retardation

In the MMR group (Table III) there were no psychiatrically unclassifiable cases, even though two boys (with

disturbances of sexual behaviour) were referred to the 'other disorder' category. Slightly less than half the children were judged 'psychiatrically normal'.

Psychotic behaviour, conduct disorder, hyperactive disorder (without 'psychotic behaviour') and emotional disorder were all common, each category accounting for 10–14% of the whole MMR group. The boy with Asperger's syndrome also had periodic mania and depression, but showed no sign of such disorders at the time of the psychiatric study.

The frequency of 'psychotic behaviour' plus MMR in the general population was estimated at 0.05% in the 13–17 year age-group.

Epilepsy

In the SMR group 27% suffered from epilepsy. There were significant differences between the psychiatrically non-disturbed and disturbed groups with regard to epilepsy. In the former group none of the children had epilepsy, whereas in the latter fully one third, had a seizure disorder ($P < 0.01$). Epilepsy was particularly common among children with psychotic behaviour.

In the MMR group 10% suffered from epilepsy. There were no clear-cut differences between psychiatrically normal and abnormal children in respect of epilepsy in this group. However, hyperactive disorders and psychotic behaviour tended to be associated with epilepsy slightly more than the other conditions (22% and 17% respectively in the two former categories, compared with 4% in other groups of psychiatrically disturbed children).

Down's syndrome

In the SMR group, Down's syndrome correlated significantly more strongly with 'psychiatric normality' than with 'psychiatric abnormality' ($P < 0.02$). However, it is worth noting that one of the Down's syndrome children suffered from classic Kanner-type infantile autism. In the MMR group there were only two children with Down's syndrome, both of whom were judged to be 'psychiatrically normal'.

Sex ratios

There was a marked preponderance of boys in the MMR group (1.9:1), but in the SMR group the difference was less marked (1.4:1). Boy:girl ratios were close to population ratios in the groups of psychiatrically normal mentally retarded children (both SMR and MMR included). In marked contrast, the boy:girl ratios were raised in the psychiatrically deviant groups (MMR: $P < 0.05$; SMR: not statistically significant), and especially in those showing either psychotic behaviour or hyperactive syndrome.

Discussion

This is possibly the first-ever systematic study of psychiatric disorders in a population-based series of

both severely and mildly mentally retarded children. The results, therefore, must be considered to be of particular interest. In the Isle of Wight study (Rutter *et al*, 1970) 50% of the severely mentally retarded children were said to suffer from a 'psychiatric disorder', on the basis of interviews with parents and observations of the children, while a further 13% were too severely retarded to qualify for a rating of psychiatric state. The only recent epidemiological study of psychiatric disorders in severely mentally retarded urban children (0–15 years) is that of Corbett *et al* (1975), who suggested that a little less than half of the severely mentally retarded children in South-East London had 'behaviour disturbance', according to results obtained at psychiatric examination of the children.

Reid (1980) tried to apply the multiaxial classification scheme for psychiatric disorders in childhood and adolescence (Rutter *et al*, 1975) to a group of 41 mildly and 19 severely mentally retarded Scottish children who attended a special child psychiatric out-patient clinic for the mentally retarded. She concluded that it was quite feasible to diagnose psychiatric disorder in mentally retarded children using the same criteria as for children of normal intelligence.

The main finding of the present study—i.e. that a high proportion (more than half) of mentally retarded children have additional psychiatric handicap conditions—taken with the evidence from the British studies, has considerable clinical implications. Child psychiatric services of a wide variety must be provided for the affected children. In Sweden there are not at present enough services to take care of the multitude of problems of individuals and families that constitute the reality behind the crude figures of this report.

However, before drawing firm conclusions several issues need to be discussed. Firstly, is the population of children studied really representative of mentally retarded children, in Sweden or elsewhere? Hagberg *et al*. (1981a, 1981b), who carried out the earlier study of mental retardation, argued that the sample is indeed representative. Certainly the reported prevalence of 0.3% SMR in our study is similar to rates found by other researchers in Sweden (Gustavson *et al*, 1977; Gillberg *et al*, 1983) and the UK (Lewis, 1929; Goodman & Tizard, 1962; Rutter *et al*, 1970) and elsewhere (Tizard, 1966). Also, the rates of epilepsy and Down's syndrome in this group are typical of groups of severely mentally retarded children (Corbett, 1981). It is thus our contention that the SMR group is a representative one. The MMR group is more problematic; we are aware that our low frequency figure (0.37%) stands out as atypical

(compared with the expected value of 2.3%), and corresponds to a mean IQ of 110–112 in the general population. Terman-Merrill (1974) attribute this secular trend of increasing IQ to cultural factors (early stimulation). Furthermore, we know that a number of children with IQs close to the cut-off point of 70 have not been included (Gillberg *et al.*, 1983). A child with an IQ of 72 at any particular time might well test below 70 at any other time. Prevailing attitudes of psychologists are of major importance in this respect; we know that in some ways the modes of application of the test methods have changed over the years. For instance, some psychologists interpret the test results in a more positive way than intended by the test manual, so that established IQ would tend to increase in the child population. Therefore, we consider our MMR group to be representative of all clearly mildly mentally children, but acknowledge the possibility that some children with IQs very close to 70 might have been missed. However, our frequencies for epilepsy and Down's syndrome are not different from those found in other studies of mentally retarded children (Rutter *et al.*, 1970; Peckham, 1974).

Secondly, how reliable and valid were the psychiatric diagnoses? The first author alone made all the final diagnoses on the basis of the information elicited at the time of the psychiatric assessment. There was more than 95% agreement between the assessors after 3–6 cases of simultaneous assessment, indicating that this information was reliable.

The same kind of psychiatric classification was recently used in a study of six and seven year-old children with perceptual, motor, and attentional deficits (Gillberg, 1983). It was concluded that the psychiatric diagnoses were both reliable and valid; the total population rates for psychiatric disorders obtained were very similar to those found in other studies of urban young children. It is thus our contention that other psychiatrists would agree that 64% of SMR and 57% of MMR children in our study had truly deviant psychiatric states.

Thirdly, how far are the findings in respect of psychiatric disorders applicable to other groups of mentally retarded children? This is heavily dependent on whether or not the SMR and MMR groups are considered representative. Since an urban child population was studied, differences might appear when compared with results from non-urban populations. Rutter *et al.* (1970) found 50% of SMR children on the Isle of Wight to have clear psychiatric abnormalities, and Corbett *et al.* (1975) found 43% of South-East London SMR children to be mentally ill. These findings, taken with ours, indicate that the frequency of psychiatric disorder in the SMR group

is not likely to be heavily influenced by differences in the rural or urban nature of the environment. Also, the type of psychiatric problem—especially those grouped under the heading of 'psychotic behaviour'—and the frequent association with epilepsy indicate that brain dysfunction (malfunction rather than loss of function (Corbett, 1985)) is responsible for much of the high rate of psychiatric disorder. All the SMR children had signs of brain damage or dysfunction (Hagberg *et al.*, 1981b).

The findings in respect of psycho-social problems have not yet been compiled, and conclusions must be drawn tentatively in this regard; this should not be taken to mean that psycho-social factors are of no importance. In the MMR group there are no sound epidemiological data with which comparisons can be made. In this group too, signs of brain damage or dysfunction occurred in more than half the cases (Hagberg *et al.*, 1981b), although the kinds of psychiatric disorder are more akin to those seen in normally intelligent children, which might infer the importance of psycho-social factor in at least some of the cases. Since psycho-social diversity is the main reason for urban children having more psychiatric disturbance than rural children (Rutter, 1975), one might expect that in rural areas one would find a lower prevalence of child psychiatric disorder than our urban 57%.

Fourthly, what do the diagnostic sub-categories imply? One half of the severely retarded and one seventh of the mildly retarded children showed 'psychotic behaviour', indicating the combination of disturbances of social relatedness, language, and behaviour seen typically in infantile autism. These proportions indicate that 0.2% of the total child population in the 13–17 age group show the combination of mental retardation and the triad of language and social impairment (Wing & Gould, 1979). This figure is the same as that found by Wing in her studies of handicapped children under 15 years old in Camberwell, South-East London. It indicates that 'autistic-like conditions' are much more common than autism, and will continue to cause problems of differential diagnosis. 'Pure' infantile autism occurs only in 10–20% of these conditions in this study and in a recent epidemiological study specifically aimed at finding autism cases in the same region (Gillberg, 1984).

All the children in the group showing 'psychotic behaviour' are in need of intense and continuous psychiatric care—some as long-term in-patients, others in the form of regular out-patient treatment or access to a specialised child psychiatric team. Many of the parents and siblings too are severely handicapped by the child's disorder—far more so

than parents and siblings of other mentally handicapped children. Special education, neuropharmacological expertise, social training programmes, family treatment (ranging from family therapy to regular contact and information), and sometimes supportive individual psychotherapy are essential features in the treatment repertoires that should be provided.

Among the children with other psychiatric disorders the degree of handicap tended to be more variable, but on the whole the psychiatric conditions were of a chronic or relapsing nature. According to medical records and other data about the children, they would have been diagnosed in the same or a similar category a year or more before the present study. This needs emphasising in view of the fact that many children in this study had reached puberty and it might be argued that the high rate of psychiatric disorder was due to this 'transient' phenomenon. It appeared that puberty sometimes tended to aggravate the problems, especially in the group with psychotic behaviour, but only rarely caused or precipitated them. However, there were three children (one with conduct disorder and two with psychotic behaviour) in the SMR group whose psychiatric problems had obviously begun at the onset of physical puberty.

A majority of the children with psychiatric disturbance had been seen for out- or in-patient psychiatric assessment during development. However, this also held true of children who were not suffering psychiatric disturbance or Down's syndrome with an IQ of around 20 or higher. Many mentally retarded children in Sweden, regardless of concomitant psychiatric disorder, are seen by child psychiatrists at an early age for assessment of their mental handicap. Child psychiatric consultation *per se*, as measured by registration at child and youth psychiatric services, is therefore not an indication of psychiatric disturbance in these children.

The degree to which epilepsy correlated with psychiatric disorder, especially in the SMR group, was striking. In this group all the epilepsy patients either were so severely retarded as to be considered

unrateable in respect of psychiatric state or were suffering from some kind of psychiatric disorder. However, almost the opposite applied in the Down's syndrome group, where psychiatric disturbance was much rarer, though the stereotype that all such children are good-natured and without psychiatric problems was contradicted by the finding that four out of the 18 severely mentally retarded children with the syndrome in this study showed 'psychotic behaviour' (including one case of infantile autism).

Boys were more often affected by psychiatric disturbance than girls; this is in keeping with research on psychopathology among normal younger children (e.g. Rutter *et al.*, 1970), but inconsistent with data from teenagers (e.g. Gillberg & Höök, 1977). The reason for the discrepancy is possibly the lower mental age in mental retardation, yielding groups which, from the developmental point of view, are comparable to pre-school and primary school age children.

This comprehensive epidemiological study of 13-17 year-old mentally retarded children in Göteborg has shown that between one half and two thirds of all such children have severe psychiatric disturbances. Differences in the frequency of psychiatric disorder between severe and mild mental retardation are small, even though there appear to be considerable differences in the nature of these disorders. In most cases the psychiatric conditions can readily be classified in terms similar to those used with children of normal intelligence, but in the severe mentally retarded group there is a sub-group in which classification is impossible. Long-term experience with mentally handicapped people is probably a prerequisite for arriving at an optimal psychiatric diagnosis. Much more effort and energy needs to go into the task of providing psychiatric services for mentally handicapped children and their parents.

Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, pheochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices.** **Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 10 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.

TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept. Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients. Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes. Most patients can be controlled with an injection at intervals of 3 weeks or more.¹ Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

FROM CLINIC...

...TO COMMUNITY

CLOPIXOL[®]

zuclopenthixol dihydrochloride/zuclopenthixol decanoate

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.

Indications Psychoses.

Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses.

Children Not recommended.

Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.

Contraindications Acute alcohol, barbiturate or opiate poisoning, intolerance to other neuroleptics. Pregnancy (relative). Use with caution in patients

with Parkinsonism, severe arteriosclerosis, senile confusion states; serious renal, hepatic or cardiovascular disease.

Overdosage Overdosage should be treated by gastric lavage.

Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. PL Nos 0458/0027,0028,0029. PA Nos 115/5/3,4,6.

CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.

Indications Psychoses, especially schizophrenia.

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.

Children Not recommended.

Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.

Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.

Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation

or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.

Package quantities & NHS price (correct of printing) 10 x 200mg (1ml) ampoules £30. 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23. PL Nos 0458/0017,0041. PA Nos 115/5/1,5,7.

Psychiatric Morbidity in First-Year Undergraduates and the Effect of Brief Psychotherapeutic Intervention—A Pilot Study

T. K. SZULECKA, N. R. SPRINGETT and K. W. DE PAUW

Out of 1279 first-year undergraduates, two matched groups of students potentially vulnerable to psychological disturbance were identified. One was left to its own resources; the other was offered psychotherapeutic intervention, the effects of which were measured by the number of consultations with general practitioners, type of treatment and rate of withdrawal from university. Although the students in the intervention group had fewer consultations, lower General Health Questionnaire scores at follow-up, and fewer withdrew from university, due to the small numbers involved none of these differences achieved statistical significance.

First-year university students are especially prone to develop psychological and personal problems. Kidd (1963) reviewed the relevant literature and emphasised that during this unknown life situation, the individual is newly confronted with the need for independence in thinking, decision-making, and actions. A new approach has to be taken in studies and in living in a student community. A balance has to be struck between the demands of the university and a freedom never before experienced. Rook (1959) pointed out that this intellectual freedom may, in the weaker members, lead to a sense of loss of direction and a feeling of inadequacy. Students who present for treatment within the first two months at university are those with more severe disturbances (Malleon, 1961; Payne, 1967; Entwistle *et al*, 1977). Davidson & Hutt (1964) analysed case records of 500 Oxford undergraduate patients and found that those who had a poor relationship with their parents, underwent previous psychological investigation, had a positive family history of psychiatric illness, and who studied English, law, music or classics, were more likely to be referred to the psychiatric services.

This paper examines the usefulness of the 28-item General Health Questionnaire (GHQ; Goldberg & Hillier, 1979) in screening a student population for psychological disturbance, and the results of offering psychological help to those first-year undergraduates who, on the basis of high GHQ scores, appear to be at risk of developing psychiatric illness. The benefit of short-term psychotherapy for such students has been discussed by Dorosin *et al* (1976), Haggerty *et al* (1980) and Pinkerton & Rockwell (1982).

The following hypothesis was proposed, that the provision of psychotherapeutic intervention has

an effect on the number of students withdrawing from the university, the consultation rate with their general practitioners, and the amount of prescriptions issued for minor tranquillisers.

Location

In 1980, 1963 students entered Nottingham University and registered in the Faculties of Arts (342), Law and Social Science (485), Pure Science (663), Applied Science (343), and Medicine (130). Most first-year students live in Halls of Residence, which provide the main focus of social life. Support for those with emotional problems may be obtained from other students, hall wardens and hall tutors, a part-time psychologist, a full-time students counsellor, three chaplains and academic tutors. The University Health Centre has four GPs who are experienced in dealing with psychologically disturbed students. They have in-patient facilities at their disposal, where minor psychological problems are treated without the necessity for formal involvement of the psychiatrist who visits the centre once a week, and to whom there is easy access at other times. A friendly and informal atmosphere at the Health Centre helps in the rapid exchange of information and expertise. Student-to-student services include a 14-hour overnight telephone counselling service called "Niteline" and for students with a homosexual orientation, weekly telephone support is available through "Gayline".

Method

The 28-item General Health Questionnaire (GHQ1) was administered to incoming students at the time of their registration with the Nottingham University Student Health Centre. All students who scored six or more on the GHQ1 were divided into two groups. The groups were matched for sex, age, subjects studied, GHQ1 scores, and the four GHQ subscores, type of relationship with parents, previous psychological investigation or help and family history of psychiatric disorder. The last three items were

determined by means of an additional questionnaire attached to the GHQ1 (Appendix), derived from Davidson & Hutt's (1964) observations, and are referred to here as vulnerability factors. The matching was carried out by a statistician who had no personal contact with any of the students. Another independent person arbitrarily designated one group as the Intervention Group (IG) and the other as the Control Group (CG). A third matched group of non-cases (MG), with the closest possible match to the IG but without vulnerability factors and with zero scores on the GHQ1, was included in the follow-up procedure to minimise the chances of the cases being identified by GPs and friends, and to provide additional comparison to the other two groups. Within the first month the IG members were invited by post for a 10–15 min individual interview which consisted of an inquiry into their feelings about the administration of the GHQ, their adjustment to university life and stresses related to separation from their families. They were also informed about the availability of support for any emotional problems, from one of the authors (TKS) doctors of the University Health Centre, or the Student Counsellor (NRS). Students who did not keep the first appointment were offered another one.

Students from the IG who asked for help had their initial interview extended, or were offered brief psychotherapy sessions with TKS, or were referred for more appropriate help. The students from the remaining two groups and those from IG who did not keep appointments were left to their own resources.

In the last month of the academic year all three groups

were individually invited to the Health Centre to repeat the General Health Questionnaire (GHQ2). Those who did not respond, despite the offer of another appointment, were visited in their Halls of Residence by TKS or KdeP. Those who had left the university had the questionnaire sent to their home.

At the end of the academic year the rate and character of consultations with the University Health Centre were studied. Each withdrawal was examined in terms of date and reason for dropping out.

Results

The GHQ1 was completed satisfactorily by 1279 students; 104 of them (8%) scored six or more (Table I).

On follow-up in the third term, three students from the IG refused contact and three others did not complete the questionnaire. From the remaining 46, 13 scored six or above (28%). In the CG, one student did not complete the GHQ; of the remaining 51, 22 scored six or above (43%). The improvement in GHQ scores was greater in the IG group, but failed to reach statistical significance.

Initial interview

Thirty-five out of 52 students (67.5%) from the IG kept their appointments with TKS. Five of the students seen (14%) expressed a need for further support, and were subsequently seen for longer interviews: two were satisfied

†Did not complete it.

with a single hour-long session each; one was seen twice more and wished to have further contact, which was not possible due to her timetable; one was referred for group psychotherapy after five one-hour consultations. The fifth student (later referred to as Student No. 1072) had already been admitted to the Health Centre and was seen on five occasions. Three students (5.7%) extended the initial contact to 40–90 min. These three were weepy, complained of sleep and concentration difficulties, and had 10 months' amenorrhoea in one case. Their distress was due to anxieties related to separation from home and pressure to develop new loyalties and friends. All but one declined immediate follow-up, but felt reassured by the knowledge of the available supportive facilities. A further two students readily acknowledged the emotional nature of their problems, e.g. difficulties in sharing a room and making friends, and an association between migraine attacks and a facial tic with psychological pressure. At first they did not desire further intervention, but consulted their GP at a later date.

Consultations with University Health Centre

The Students' Health Centre had 9883 NHS registrations

in 1980 and 9017 in 1981. In the period from 1 August 1980 to 31 July 1981, 16 115 consultations with a GP were made: 62% of these consultations were made by undergraduate students. The consultation rate for those who saw a doctor was 4.1 per person per year.

Twenty-eight IG students made 125 consultations (mean 2.3); 12 were classified by the GP as psychiatric (three individuals), 13 were due to trauma, 21 students never consulted their doctors, and three case notes were not available for examination. Twenty-seven CG students made 148 consultations (mean 2.9), 15 were psychiatric (11 individuals), five were due to trauma and four case notes were not available. Thirty-one students from MG made 104 consultations; of them, one had two psychiatric consultations, 15 were due to trauma (eight students), 19 never consulted their doctor, and two case notes were not available for examination. Missing case notes were unavailable as they had already passed to the home GP after the student's withdrawal from university. None of the students received prescriptions for minor tranquillisers. The mean number of consultations per person per year for those who consulted a doctor was 4.3, 4.0 and 3.3 for IG, CG and MG respectively. None of the differences were statistically significant.

Withdrawals

Table II shows withdrawals from IG, CG and MG.

Of the four students who withdrew from the IG, two were seen by TKS. One student (No. 1072) was already an in-patient at the Health Centre at the time of the initial interview with a diagnosis of paranoid psychosis and she was later transferred to a local psychiatric hospital. At the 10-month follow-up her GHQ score remained high, and 13 months later she was still incapable of resuming her academic career. Another student (No. 0035) complained of suicidal thoughts and of dissatisfaction with various aspects of life on entering university, but turned down an offer of further help. He saw his GP on four occasions, complaining of headaches. In June his father suggested psychiatric help, but the student withdrew in July without taking any exams or seeing a specialist. The two remaining students (Nos 0854 and 0866) did not keep their appointments with TKS; they both scored 22—the highest score of those tested.

Table III summarises the effects of intervention.

Discussion

The main effect of the psychotherapeutic intervention offered was reflected by the number of definite psychiatric consultations with GPs. The CG group consulted more frequently but group members were

not persistent in seeking help. This could have been due to the fact that they were sufficiently helped by a single consultation, or more likely were satisfied with a single reassurance. In the IG group, this role was taken by TKS, and only those in need of more intensive help consulted their GP's at a later stage. If early intervention did nothing else but reach those in need of reassurance, in a group identified by high scores on the GHQ1 one in six students needed it. If both the GHQ and vulnerability factors were combined in an effort to identify the group needing help, the results could have been more dramatic. Unfortunately, in this pilot study, the consultation rate of students with various vulnerability factors was not examined. However, on the basis of their increased rate of psychiatric morbidity (Davidson & Hutt, 1964) and increased withdrawal rate, we can draw the conclusion that both the GHQ and vulnerability factors are useful tools in identifying students in need of psychotherapeutic help.

Our findings indicate that first-year students use the University Health Centre to the same extent as the rest of the population, and that students with increased GHQ scores do not consult their doctors more often, despite being in need. This was confirmed by our own observations of their reluctance

to become involved with helping agencies, and supports the view that students with academic problems also tend to avoid seeing advisers (Nisbet & Welsh, 1976) and are more reticent about disclosing personal information (Hall *et al.*, 1982). Therefore, our initiative to get in touch with students in need increased the chances of reaching those who would otherwise have been reluctant to seek help.

Students who were seen in the third term approved of the use of the questionnaire—but later in the first term, when newcomers might have overcome their first anxieties about settling into university life. They saw it as evidence of care, and it strengthened their confidence in the Health Centre, reflected in the relatively high consultation rate for the first-year students. Cobb (1976) has defined support as 'information leading the subject to believe that he is cared for and loved, esteemed, valued, and accepted'. For the majority of our students, the screening procedure implied that "somebody bothered", but extreme reactions in both directions were present, ranging from a resentment at intrusion into private areas to a feeling of gratitude.

GHQ scores or suspected psychological vulnerability were not disclosed to students during the interview: only when students themselves expressed a wish for help were their problems discussed. It remains an open question whether such a disclosure would have been of any help or would only have added another psychological burden. As Lucas *et al.* (1966) have pointed out, it is difficult to find the right level of intervention. Determining valid measures of improvement in any psychotherapeutic intervention remains problematic (Candy *et al.*, 1972; Bloch *et al.*, 1977; Adams, 1978; Prioleau *et al.*, 1983; Shepherd, 1984) and is even more difficult in brief contacts such as in this study.

The withdrawal rate for the intervention group (9.7%) was lower than that of the control group (11.5%), but this failed to reach statistical significance.

The reduction of the withdrawal rate from university through psychological intervention was possibly not more striking not only because of the small numbers involved, but also because in 67.5% of those who responded, preselection of less vulnerable cases took place, and only those who expressed a need for help were offered it. Confidentiality prevented disclosure of the results to GPs and jeopardised involvement of those who were more readily available to students at the later stage. Student No. 0035 seems to be a good example of this. His withdrawal could perhaps have been prevented by alerting the GP to his psychological problems. This demonstrates the potential usefulness of

prior knowledge of GHQ scores and 'vulnerability factors' as a means of alerting GPs to the somatic presentation of primary psychiatric disturbance which is so commonly found in a general practice population (Goldberg & Huxley, 1980). The two students who never kept their appointment with TKS were further examples of those who resist any offer of help; they either demonstrate the limits of such an approach in this group or emphasise the need for a more determined follow-up. Student No. 1072 had a major psychiatric disorder and was in need of more intensive psychiatric help than short intervention.

Students themselves stressed the advantage of discussing problems with their peers. All psychotherapeutic factors in a spontaneously organised group would then seem to come into play (Yalom, 1975) and many of them were relieved to discover that they were not isolated in their distress. Facilitation of such naturally occurring self-help groups in halls of residence could be an appropriate way of helping vulnerable students. Its therapeutic value could be increased by involving tutors normally responsible for a defined group of students who can be brought together without fear of being labelled as psychiatrically disturbed. This would also increase involvement in the student community itself, would aid integration into university life, and possibly reduce the drop-out rate from university (Tinto, 1975). It is striking that three students (6%) from the MG failed their examinations and that none left the university of their own accord. Ryle (1969) indicated that academic underachievement in emotionally stable students could be due to the anxiety levels being too low for efficient work. The lack of change in the GHQ2 scores in our sample, despite academic problems, supports this theory further. The MG performance and rate of failure might have been influenced by additional academic pressures.

Acknowledgements

We wish to thank the students who took part in this study, as well as the Cripps Health Centre, Mrs M. J. Anderson, Dr I. Flowers, Cripps Computing Centre, Drs P. C. McLean, R. J. Turner, P. Tyrer and D. C. Watt, Mrs Sally Abbott, Miss L. Ridley-Thompson, and Miss J. A. Zuranska. This work was supported by a grant from the Trent Regional Health Authority.

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine,¹ trifluoperazine² and haloperidol³ but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia⁴

DolmatilTM sulpiride
IN SCHIZOPHRENIA

Prescribing information Dolmatil Tablets: Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other. Each tablet contains 200mg sulpiride. **Indications:** Acute and chronic schizophrenia. **Dosage:** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning and early evening) is recommended. **Predominantly positive symptoms:** Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice daily. **Predominantly negative symptoms:** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily. **Mixed positive and negative symptoms:** 400mg-600mg twice daily. The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment. Clinical experience in children under 14 years of age is insufficient to permit specific recommendations. **Contraindications:** Pheochromocytoma. **Warnings:** Extrapyramidal reactions principally akathisia have been reported in a small number of cases. If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary. After over a decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at high dosage in a small number of patients. In aggressive, agitated or excited phases of the disease process, 'Dolmatil' may aggravate symptoms. Care should be exercised where hypomania is present. Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions:** Epilepsy - anti-convulsant therapy should be continued unchanged. Impaired renal function, as sulpiride is eliminated via the kidney. Pregnancy - the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed. **Product Licence Number:** PL 5299/0006. **Legal category:** POM. **Basic NHS cost:** 63p per day at dose of 600mg daily. **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. **Trade Marks of E R Squibb & Sons Ltd (Distributor) DOLMATIL -** Trade Mark of SESIF Authorised User Delagrang Ltd. **References** 1. A SCHIZOPHRENIC.

Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.

A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*
haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼ **Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. **Use in Pregnancy:** The safety of haloperidol in human pregnancy has not been established. **Precautions:** Caution in liver disease, Parkinson's disease, pheochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyl dopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. **Side Effects:** In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50–100mg every 4 weeks; in moderate symptomatology 100–200mg every 4 weeks; in severe symptomatology 200–300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from Janssen Pharmaceutical Limited, Grove, Wantage, Oxon OX12 0DQ.

Bowden House Clinic— back on the map.

Bowden House Clinic, now part of the St Andrew's Hospital Group of private psychiatric hospitals, has specialist in-patient and out-patient treatment programmes for:

- **Acute psychiatric disorders**
- **Alcohol problems**
- **Anorexia nervosa and other eating disorders**
- **Agoraphobia**

As well as the newly established
North-West Home Counties Psychotherapy Centre

Bowden House Clinic, set in attractive, secluded grounds at Harrow-on-the-Hill, is only 30 minutes by road or rail from central London.

Subscribers to private medical insurance schemes may be able to claim within the terms of their insurance for treatment at the clinic.

BOWDEN HOUSE CLINIC

For further information, write to

The Medical Director, Bowden House Clinic, London Road, Harrow-on-the-Hill, Middlesex HA1 3JL. Tel: 01-864 0221

Autism and Autistic-like Conditions in Swedish Rural and Urban Areas: A Population Study

SUZANNE STEFFENBURG and CHRISTOPHER GILLBERG

The total population of children under 10 years in one Swedish urban area and one rural area was screened for infantile autism (IA) and autistic-like conditions (AC). A total prevalence of 6.6 per 10 000 was found, which is somewhat higher than in previous similar studies of the same region. Infantile autism accounted for two-thirds of the cases. Boys far outnumbered girls, but this was entirely accounted for by the IA group. The preponderance of autistic boys was less pronounced among the severely mentally retarded children. Mental retardation was seen in almost 90% of cases and only one child had an IQ exceeding 100; clinical and laboratory signs of brain dysfunction were also found in a majority of cases. Distribution by social class was no different in either patient group from the general population.

To our knowledge there exist four published population-based studies of infantile autism and similar conditions (Lotter, 1966; Wing & Gould, 1979; Gillberg, 1984; Bohman *et al.*, 1983). These have all yielded fairly consonant results, with frequency figures ranging from 4 to 6 per 10 000 children, 'nuclear autism' accounting for about half of these. The frequency figures are almost stunningly similar in view of the well known fact that the diagnosis of infantile autism continues to cause controversy. Wing & Gould (1979) made claims for a new diagnostic category, viz. 'the triad of language and social impairments', in which they included cases of 'nuclear autism'. They found frequency figures for this triad of 21 per 10 000 in a south-east London borough. Gillberg, working in Gothenburg, Sweden, obtained exactly the same figure for the estimated frequency of the triad in the general teenage population (21 per 10 000) by extrapolating from studies of the mentally retarded (Gillberg *et al.*, 1986); and an even higher estimate for the general population when children with minor neurodevelopmental disorders were screened (Gillberg, 1983a). The studies by Wing and Gillberg show that there exist a number of children with syndromes similar to infantile autism in terms of both symptomatology and needs for services, and both these authors have argued for 'a spectrum view' of autism. However, both authors agree with Rutter (1978) in acknowledging the existence of a core group of classically autistic children within this spectrum. These are the kinds of children originally described by Kanner (1943) and said to fulfil the crucial diagnostic criteria of autistic aloneness and

stereotyped behaviour (elaborate routines) suggested by Kanner & Eisenberg (1956).

Two of the population-based studies originated in Sweden. These might be considered to be of special interest, as they represent investigations performed in areas with quite different social structures and were performed by researchers who discussed diagnostic criteria in some detail. The study by Bohman *et al.* (1983) was performed in the late 1970s in an almost exclusively rural area in northern Sweden, whereas the one by Gillberg was done in the same period in a large industrial urban area in the south-west of Sweden. The rural study came up with a frequency for 'childhood psychosis' of 6 per 10 000, 'classical autism' accounting for half of the cases. The urban study, on the other hand, yielded a corresponding figure of 4 per 10 000, 'infantile autism' cases again constituting about 50%. The difference between the results of these studies might prove to be due to chance; or it might turn out to be important, considering the well known facts that child psychiatric problems in general are very much more common in urban than in rural areas (Rutter *et al.*, 1970; Rutter, 1975) whereas mental handicap tends to be distributed the other way around.

Gothenburg and its neighbouring rural area (the county of Bohuslän) now provide unique possibilities for population-based studies of infantile autism and similar conditions. We performed population screenings in 1978 and 1980 and these paved the way for intensified detection and diagnostic services in the area. We therefore considered it of special value to perform new population screenings in these areas, in order (a) to shed some further light on the issue

of diagnosis, and (b) to analyse the importance of certain demographic factors in autism and autistic-like conditions.

Definitions

Infantile autism (IA) was defined in accordance with the criteria of the DSM-III (A.P.A., 1980), which requires:

- (a) Onset before 30 months of age
- (b) Pervasive lack of responsiveness to other people (autism)
- (c) Gross deficits in language development
- (d) If speech is present, peculiar speech patterns such as immediate and delayed echolalia, metaphorical language, pronominal reversal
- (e) Bizarre responses to various aspects of the environment, e.g. resistance to change, peculiar interest in or attachments to animate or inanimate objects
- (f) Absence of delusions, hallucinations, loosening of associations, or incoherence, such as are found in schizophrenia.

All children with IA also fulfilled the criteria of both Rutter (1978) and Coleman & Gillberg (1985) for infantile autism. In the following text this diagnostic entity is also referred to as 'autism' or 'autistic syndrome'.

Autistic-like conditions (AC) were defined as conditions similar to IA in respect of symptomatology, but either showing some highly atypical traits (e.g. extremely clinging behaviour or confusion) or commencing after the age of 30 months (according to medical/psychological record data). What we refer to as 'autistic-like conditions' have been referred to as 'other childhood psychoses' in previous publications.

Method

Populations studied

Urban: All children born during the years 1975–1984 and living in the city of Gothenburg on 31 December 1984 constituted the urban target population. The total number of children in this population was 42 886 (21 949 boys and 20 937 girls).

Rural: All children born during 1975–1984 and living in the county of Bohuslän on 31 December 1984 constituted the rural target population. The total number in this population was 35 527 (18 268 boys and 17 259 girls).

Organisation of services for autistic children in Gothenburg and Bohuslän

During the last ten years diagnostic and treatment facilities

for 'psychotic' children have been rapidly developed in Gothenburg and Bohuslän. The second author (C.G.) has performed two major screening studies, one in 1978 and the other in 1980. These have led to markedly increased interest in autism and similar conditions among paediatricians, child psychiatrists, child neurologists, audiologists, well-baby clinic personnel, school health officers (doctors, nurses and psychologists), teachers, and officials concerned with mental retardation. Both authors have given lectures on autism to all these categories of professionals, and the symptoms of autism and autistic-like conditions as they appear from infancy through childhood have been described in some detail.

At the present time, most children in Gothenburg and Bohuslän who are suspected of suffering from autism and autistic-like conditions are referred to the second author for a diagnostic evaluation. Six or seven years ago, many autistic and autistic-like children were referred for the first time only after the age of seven years. Nowadays, most children with autism have their condition diagnosed at a much earlier age, often at 1–2 years, very rarely after age 5 years.

In Sweden the child health services encompass 99% of all children, who have regular medical check-ups almost every year before age 10 years. Before starting school they are seen at age 6 years by a clinical psychologist. All children known to the Board for Provisions and Services to the Mentally Retarded (BPSMR) have medical check-ups yearly.

It is improbable that any large fraction of children with autism or autistic-like conditions could escape recognition in a region where coverage is so nearly complete and knowledge in this particular field is at a fairly high level.

Questionnaire screening

In November 1984, a letter of information and a questionnaire were distributed to all paediatricians, child psychiatrists and doctors working in the institutions for the mentally retarded, phoniatric/audiology departments, school health authorities and well-baby clinics in the city of Gothenburg and the county of Bohuslän, with the request that the questionnaire be completed and returned within two months. All schools (including special schools for autistic, mentally retarded, maladjusted, blind and deaf children) are regularly surveyed by paediatricians, child psychiatrists, ophthalmologists or audiologists. This meant that the screening by questionnaire was not limited to children referred to clinics. Furthermore the second author (C.G.) is in charge of the medical section of the BPSMR (covering Gothenburg and Bohuslän) and of services and schools for autistic children within the Child Psychiatric University Clinic in Gothenburg. This means that he has himself examined all possibly autistic or definitely autistic children attending schools for mentally retarded and autistic children in Gothenburg and Bohuslän.

Each doctor receiving a questionnaire was asked if he/she (or any of his/her collaborators) knew of any child born in 1975 or later with 'infantile autism, childhood schizophrenia, childhood psychosis, mental retardation

with autistic traits, severe disturbance of social relationships plus speech-language disorder, or severe compulsive disorder'. The doctor was requested to state the child's diagnosis, give a short description of the symptoms, report age of onset, summarise tests and other investigations, describe treatment given, and also describe the type of dwelling and the school attended by the child. Through the questionnaire we also reached all clinical child psychologists working in the region, as they all work in close collaboration with the doctors we contacted. All persons (doctors, psychologists, social workers, teachers, physiotherapists, etc.) known to be involved with services for psychotic children were contacted personally by the second author and interviewed in accordance with the questionnaire.

Register search

The registers of the child psychiatric/child guidance clinics, paediatric clinics and the BPSMR were searched in

January 1985 in order to identify cases of 'infantile autism', 'childhood psychosis', 'childhood schizophrenia' and 'mental retardation with autistic traits'.

Diagnostic procedure

All children reported were either dismissed as 'non-suspected' cases after we had conducted a thorough interview with the reporting doctor, psychologist or teacher, or were personally assessed by the second author (C.G.). more than 90% of the reported cases were known to the second author already before the questionnaire screening.

Clinical assessment

All children known by the second author personally to suffer from infantile autism and similar conditions had previously been thoroughly examined by him. All the case records (medical and school reports) of these children were re-analysed.

TABLE I
Number of cases of infantile autism (IA) or autistic-like conditions (AC) in Gothenburg (urban) and Bohuslän (rural) at the end of 1984

Year of birth	IA		AC		Total (IA + AC)		
	Gothenburg	Bohuslän	Gothenburg	Bohuslän	Boys	Girls	All
1975-1977	7	12	6	2	22	5	27
1978-1980	10	2	6	1	13	6	19
1981-1984	3	1	0	2	4	2	6
Total	20	15	12	5	39	13	52

TABLE II
Prevalence figures for infantile autism (IA) and autistic-like conditions (AC) in Gothenburg (urban and Bohuslän (rural) at the end of 1984 (among children born 1975-1984)

Diagnostic group	Gothenburg	Bohuslän	Total
Infantile autism			
prevalence	4.7/10 ⁴	4.2/10 ⁴	4.5/10 ⁴
boy:girl ratio ¹	5.4:1	6.1:1	5.7:1
Autistic-like conditions			
prevalence	2.8/10 ⁴	1.4/10 ⁴	2.2/10 ⁴
boy:girl ratio ¹	1.0:1	1.4:1	1.2:1
IA + AC combined			
prevalence	7.5/10 ⁴	5.6/10 ⁴	6.6/10 ⁴
boy:girl ratio ¹	2.4:1	3.8:1	2.9:1

¹Population-based ratio, adjusted to allow for boy girl ratio in the general population

TABLE III

Intellectual levels (IQs) of boys and girls with infantile autism (IA) and autistic-like conditions (AC): urban and rural areas combined

Intellectual level	IA		AC		IA + AC	
	n(%)	boy:girl	n(%)	boy:girl	n(%)	boy:girl
IQ < 50	21(60%)	16B:5G	9(53%)	4B:5G	30(58%)	20B:10G
IQ 50-70	10(29%)	10B:0G	6(35%)	5B:1G	16(31%)	15B:1G
IQ > 70	4(11%)	4B:0G	2(12%)	0B:2G	6(12%)	4B:2G
Total	35(100%)	30B:5G	17(100%)	9B:8G	52(100%)	39B:13G

Children suspected of suffering from psychosis on the basis of the questionnaire reports and not known by the author were assessed using routine clinical child psychiatric techniques. Relevant case records were collected and scrutinised.

A majority of the children in the study had already been tested with the Griffiths Developmental Scale for Children (Griffiths 1970) and the Vineland Social Maturity Scale (Magne & Wahlberg, 1961). The remaining children had been considered untestable and were judged clinically to be severely mentally retarded (IQ less than 50). The Autism Behavior Checklist (Krug *et al.*, 1980) and a newly constructed interview schedule pertinent to the study of autism were used to elicit relevant information in all cases.

A diagnosis of infantile autism (IA), autistic-like condition (AC), or 'non-autistic/non-autistic-like' was assigned in each case.

conditions (Table II). Infantile autism was considerably more common than autistic-like conditions (4.7 versus 2.8 per 10 000).

Bohuslän (rural). The prevalence for IA and AC combined in the rural county was 5.6 per 10 000. IA was more frequent than AC, accounting for 4.2 per 10 000 children.

Intellectual level

Slightly more than half of the children were severely mentally retarded (Table III). One-third of this group consisted of children with tested IQs in the 40-50 range. A large majority of the remainder had developmental or social quotients below 30. About 15% of the children were of normal or near-normal intelligence.

Statistical methods used

Chi-square tests were used in the statistical analyses of the results.

Results

Numbers of children with IA and AC Gothenburg (urban): There were 20 children (17 boys and 3 girls) with infantile autism in Gothenburg (Table I). Of these, only three were aged 4 years or under at the time of the study. Twelve more children (6 boys and 6 girls) with autistic-like conditions were identified: all of these were aged 5 years or older.

Bohuslän (rural) There were 15 children (13 boys and 2 girls) with IA in Bohuslän. One of these was under 4 years old. A further five children (three boys and two girls) were found to have AC: two of these were under 4 years old.

Population prevalence

Gothenburg (urban): Altogether 7.5 per 10 000 of all children in Gothenburg suffered from autism or autistic-like

TABLE IV

Obvious clinical organic signs of handicap associated with infantile autism (IA) and autistic-like conditions (AC): urban and rural areas combined

Clinical sign	IA (n=35)	AC (n=17)

Total number at Children	14(40%)	8(47%)

¹Several more children had other chromosomal abnormalities

Boy:girl ratios

In the autistic group the boy:girl ratio was 5.7:1 after adjustment for the boy:girl ratio in the general population. In the group with autistic-like conditions the corresponding ratio was 1.2:1. Among the severely mentally retarded children (IQ < 50) the boy:girl ratios were much lower than among those with milder degrees of intellectual retardation: this trend was particularly pronounced in the autistic group.

Associated handicaps

Two-fifths of the autistic group and almost half of the group with autistic-like conditions had 'obvious clinical organic signs' (other than mental retardation) indicative of CNS-dysfunction (Table IV). A majority of the children in both groups had radiological, physiological or chemical signs of nervous-system damage or dysfunction.

Almost a quarter of the children had developed epilepsy (Table IV). This was much more common in the group with AC. Two-thirds of the children with seizures were girls. Ten of the 12 children with epilepsy had had an onset of seizures before 12 months.

Three autistic boys suffered from congenital bilateral palsy of the facial nerves (Moebius syndrome) and another three had the Martin-Bell syndrome with some or all the physical characteristics of that diagnostic entity and the fragile (X) (q273) chromosomal abnormality.

TABLE V

Analysis by social class of children with infantile autism or autistic-like conditions, compared with a random sample of 7-year-olds from the general population. There were no statistically significant differences between the three groups

Social class	IA	AC	General population
I	1(3%)	1(6%)	4(7%)
II	10(29%)	6(35%)	24(41%)
III	24(68%)	10(59%)	31(53%)

Social class

There was no obvious or significant social-class bias (class assessed according to father's occupation: Swedish Central Bureau of Statistics, 1968) in either the IA or the AC group when contrasted with a randomly selected group of normal seven-year-olds (this latter group is described in detail in Gillberg & Schaumann, 1982). If anything, there was a slight trend towards lower social class among the autistic and autistic-like children (Table V).

Discussion

This population-based study of autism and autistic-like conditions yielded higher prevalence figures

than an almost identical study performed a few years earlier by the same team in the same region (Gillberg, 1984). The previous study found a total of 4.0 such children per 10 000, infantile autism accounting for half the cases: the new study showed a total prevalence of 6.6 per 10 000, infantile autism accounting for two-thirds of the cases. The higher prevalence is probably due to better detection of cases in the new study. It is highly unlikely that autism has become relatively much more common in only five years. The prevalence figure obtained now is very close to that found by Bohman *et al* (1983) in northern Sweden, in another area with good coverage and relatively well-developed assessment facilities.

In our region, 'autism detection sensibility' has been raised most particularly among those working with the mentally retarded from 1980 through to 1984: almost all of the 'extra' prevalence of autism and autistic-like conditions found in this study compared with our previous ones is accounted for by severely mentally retarded children. The prevalence of autism and similar conditions among mildly retarded and normally intelligent children is almost exactly the same as in the previous studies.

There were slight (though statistically insignificant) differences in prevalence between urban and rural areas, with urban prevalence being higher. Whether these findings reflect real differences or dissimilarities with regard to coverage and assessment facilities is not yet known. This difference in prevalence does not accord with previous suggestions (Gillberg, 1984) that autism might be more common in the countryside than in cities.

The tendency for 'autism' to be a more common diagnosis than 'autistic-like conditions' (or 'other childhood psychoses') is probably a result of increasing awareness of the early symptoms, leading to early referral. As in our previous studies, our diagnoses of infantile autism did not rely on medical records except to confirm the presence of central symptoms before age 2½ years.

We would argue for the abolition of the term 'other childhood psychoses' when referring to autistic-like conditions: the major clinical signs and symptoms in these groups of children really do qualify them for the description of 'autistic-like'. True, there exist symptoms not typically seen in autism (such as confusion and extremely clinging behaviour) and the onset is usually somewhat later than in infantile autism, but the similarities are really overwhelming.

The boy:girl ratio is considerably higher in this study than in our previous ones. An overall ratio of 2.7:1 was found this time, compared with 1.8:1 four

years ago. Infantile autism was found by this study to be more than five times as common in boys as in girls, whereas autistic-like conditions tended to be only marginally more common among boys. As in Lorna Wing's study (Wing, 1981) and our own previous studies, there was a clear trend towards decreasing boy:girl ratios with decreasing IQ. In spite of our efforts to reach all possibly autistic children in the areas studied, we are aware that we might have missed some very young autistic children and a few with very high IQ levels. We do not believe, however, that any considerable fraction of mentally retarded children with autism or autistic-like conditions could have been missed.

A third of the IA and half of the AC children had obvious clinical organic signs such as epilepsy, tuberous sclerosis, neurofibromatosis and the fragile (X) syndrome. Almost all the autistic children showed clinical, radiological, neurophysiological or neurochemical signs indicative of central nervous system damage/dysfunction (Gillberg, 1985). These results are in sharp contrast with those presented in the early days of infantile autism, when the disorder was supposed to be psychogenic.

Social class did not differentiate either of the index groups from a comparison group of primary-school-age children without major handicaps. If anything, there was a trend (statistically insignificant) towards infantile autism being relatively more common in low social classes. This result accords

well with modern studies of social factors in infantile autism (Wing, 1980; Gillberg & Schaumann, 1982; Bohman *et al.*, 1983). There is now a convincing body of evidence from population-based studies that infantile autism is *not* associated with high social class, and we hope that the fruitless arguments about this issue will finally come to an end.

Finally, we would like to draw attention to the fact that there exist other children, far outnumbering those in the present study, with 'autism spectrum' problems or 'autistic traits'. These have been referred to as children with 'psychotic behaviour' (Gillberg, 1983a, 1983b) or 'the triad of language and social impairment' (Wing & Gould, 1979). Among severely mentally retarded children these traits occur fairly often (Gillberg *et al.*, 1986) and they are also seen frequently in children with moderate degrees of motor-perceptual disturbance. No attempt was made in this study to detect all such cases.

Acknowledgements

We are grateful to all the doctors, psychologists and teachers who kindly provided the necessary data, and to Mrs Gun Jakobsson and Doris Andrén for secretarial assistance. The study was supported by a grant to C.G. from the Swedish Medical Research Council (B85-21P-6750-02).

Two Stage Design in a Community Survey

J. L. VÁZQUEZ-BARQUERO, J. F. DÍEZ-MANRIQUE, C. PEÑA, R. G. QUINTANAL and

M. LABRADOR LOPEZ

By comparison with the PSE-ID system, we showed that the GHQ-60 could be used with good results as a screening instrument in the first of a two stage community survey. Unlike the sensitivity and negative predictive values, the specificity and positive predictive rates reach low figures in this study. The global efficiency and positive and negative predictive values of the test are significantly improved by raising its cut-off score, but at the expense of great reduction in sensitivity. The revised scoring system failed to provide better prediction of 'caseness' than conventional scoring. The GHQ does not distinguish fully between persons in the community afflicted by 'transient states of distress' and those whose symptoms would classify them as 'cases' by the PSE.

There is a widespread consensus that statistics derived from patients under treatment give a very incomplete estimate of the total psychiatric morbidity of the community, because of the many factors affecting the recognition and declaration of illness. To overcome this bias, a measurement of untreated morbidity is required, and a very appropriate research strategy for such measurement is the two stage screening survey (Eastwood, 1971; Vázquez-Barquero, 1978; Duncan-Jones & Henderson, 1978; Deming, 1977). In the first stage, the population under study is classified, usually by means of a questionnaire, in terms of the probable presence or absence of psychiatric pathology. In the second, a variable proportion of 'probable cases' and at times also of 'non cases' has to be examined by a psychiatrist, in order to make a definitive diagnostic evaluation.

The decision to integrate psychiatric screening into the community surveys has the implication of having to select for the analysis of morbidity two different instruments, (screening questionnaire and psychiatric interview), whose efficiency and reliability should be estimated by testing them jointly. Widely recommended instruments are the General Health Questionnaire, GHQ (Goldberg, 1972; Goldberg, 1978) and the Present State Examination, PSE (Wing *et al.*, 1974).

The GHQ was originally designed for identifying mental illness in general practice (GP). It has been shown to possess high levels of validity in different medical settings (Goldberg, 1972, 1978; Maguire *et al.*, 1974; Ballinger, 1975; De Paulo *et al.*, 1980; Nott & Cutts, 1982; Hobbs *et al.*, 1983). These high validity figures have also been confirmed by us in two

Spanish medical samples (Muñoz *et al.*, 1978; Vázquez-Barquero *et al.*, 1985). In all these, however, the diagnosis of 'case' was established through the Clinical Interview Schedule, CIS (Goldberg *et al.*, 1970). This interview, although capable of achieving high reliability, is reported to produce a lower threshold for case identification than the one used with the PSE-ID system. This appears to be due to the fact that these two instruments were developed in completely different ways. While the concept of 'case' incorporated in the CIS was derived from primary care patients the PSE was based on psychiatric in-patient populations; therefore, if one wishes to obtain comparable data, it appears necessary to use a higher cut-off point for the GHQ, when used alongside the PSE-ID (Finlay-Jones & Murphy, 1978; Goldberg, 1981).

Different studies have tested the GHQ using the PSE-ID as external criterion of validity. Newson-Smith & Hirsch (1979) reported a highly significant correlation (0.80) between the two instruments in interviews with self-poisoning patients. Finlay-Jones & Murphy (1979) validated the GHQ-30 in two samples of women in a GP setting. They found that compared with the shortened version of the PSE, the GHQ misclassified 26% of respondents. False positives were suffering from physical illness, loneliness, and recent life events, while false negatives tended to be women with chronic psychiatric disorders mainly anxiety. Rabins & Brooks (1981), relying on a subjective evaluation of information gathered with the PSE, found that the GHQ-28 was a valid instrument (correlation coefficient: $r=0.83$; sensitivity: 92%; specificity: 92%) for detecting emotional morbidity in patients attending a multi-

ple sclerosis clinic. Robinson & Price (1982), used a modified version of the PSE, in a sub-sample ($n=30$) of 103 patients attending a stroke clinic. They found that the total score of GHQ-28 correlated highly with a depression scale derived from the PSE ($r=0.88$). In a recent study by Byrne (1984) 211 women referred to a gynaecological out-patient clinic were screened for psychiatric disorders on the GHQ-60. A random sub-sample ($n=35$) of these women were interviewed, at a second stage, using the PSE. In this group, the specificity of the GHQ was 86%, the sensitivity 67%, false positives 20%, and the overall misclassification rate 26%.

Two major validity studies tested the screening capacity of the GHQ in general population samples. Banks (1983) sampled 200 17 year olds; he confirmed that different versions of the GHQ correlated highly with the PSE-ID. Duncan-Jones & Henderson (1978) incorporated both instruments into a two-stage strategy of analysis of a general community sample in urban Canberra. They found a high correlation between PSE and GHQ scores (0.76); however, a certain number of high scorers on the first stage were not confirmed as 'cases' by the PSE on the second stage. This was thought to be partly related to applying a more stringent criterion of caseness than the one used in the original Australian validity study (Tennant, 1977), and partly due to the fact of some respondents changed their illness status from ill to well during the two-stage interval. It was concluded that the combined use of these two instruments provides a rigorous description of morbidity but an upward revision of the GHQ cut-off score was recommended when used alongside the PSE-ID system.

We describe here an attempt to test the performance of the GHQ-60 as a screening instrument against the PSE-ID in a two-stage community survey; this is part of a mental health survey, which we are conducting in a sea-side rural community of Santander (Cantabria), Spain.

Method

Design

The design was based on a two stage (screening questionnaire and psychiatric interview) cross-sectional analysis of a representative sample of the population studied.

Description of the area

The area under study consists of three adjoining counties, on the eastern side of the bay of Santander. This area extends for approximately 105 km² and has a current population of approximately 9,250. This community was

chosen to represent the non-urban coastal part of the province; it has a mixture of dairy farming, fishing, light industry, and tourist activities.

Subjects

(a) First stage

A random sample of 1250 names was drawn from an electoral register of the three counties, and thus exclusively of persons over 17 years of age. Special care was taken to make sure that each name had equal chance of being selected.

At this stage, all the subjects were visited by a team of interviewers, who were specially trained final year medical students. During a single session, each person was asked to complete the GHQ-60 items, as well as a range of medical and social questionnaires.

The GHQ score was calculated by using the non-weighted GHQ method: the cut-off score of 11 was used, above which the patient is considered to be a 'probable psychiatric case' (Goldberg, 1978). Below-threshold schedules were allocated into two different batches in terms of GHQ score, giving a breakdown of the population into 0-5 and 6-11 scorers.

(b) Second stage

The criterion for the selection of subjects to be included at this stage was: (i) All subjects who scored 12 or more, on the GHQ ('probable positives') in the first stage. (ii) An approximately equal number who scored below 12 ('probable negatives'); this second group was selected at random from each batch of below-threshold schedules returned from the first stage. The description in numerical terms of this sampling method is shown in Table I.

The subjects selected at this stage were interviewed in their homes within the following month (between 23 and 45 days after; $\bar{X}=34.2$, S.D.=5.37) by a team of psychiatrists, using the ninth edition of the PSE (Wing *et al*, 1974). They had been trained in the use of the PSE by medical staff from the MRC Social Psychiatry Unit at the Institute of Psychiatry, London. At the time of the interview the psychiatrists were unaware of each persons' answers to the GHQ and to other psychopathological instruments.

The PSE data were analysed using the CATEGO program (Wing *et al*, 1974) and the Index of Definition, ID (Wing *et al*, 1978). The ID allows eight degrees of definition of symptomatology to be established; at the threshold and definite levels (5-8), disorders are sufficiently well defined as to be considered pathological. Subjects could also receive a CATEGO diagnosis.

Because of the stratified sampling in the second stage, the prevalence figures have to be weighted to reconstitute the original sample (Table I). This was done by applying the following mathematical formula:

$$\text{Prevalence} = \frac{\sum \frac{e_i n_i}{m_i}}{N}$$

e_i = number of cases detected in each of the three batches of GHQ score (0-5; 6-11; ≥ 12) for the group under analysis.

n_i = number of persons in the first stage sample in each batch of GHQ score for the group under analysis.

m_i = number of persons in the second stage sample in each batch of GHQ score for the group under analysis.

N = total number of persons in the first stage sample for the group under analysis.

Chi-square analysis was used to compare rates, while Student's *t*-test was performed to compare groups mean values.

Results

Table I shows the distribution of subjects in the first and second stages, according to their sex and GHQ score. Six females scoring 12+ on the GHQ, as well as some others 'low scorers' (three female, seven male) refused to collaborate in the second stage, and had to be substituted. It was also necessary to replace three more 'low scorers' (two male, one female) because of incomplete data. All

the substitutes were selected randomly from the group of persons scoring below threshold at the first stage. In spite of the substitutions, a proportional representation of the two levels of low scorers detected in the first stage was maintained in the second.

Psychiatric morbidity

The measurement of morbidity by the PSE-ID system found in the second stage for the different GHQ scores is shown in Table II: 149 (32.7%) persons had no symptoms (ID level = 1), 181 (40.3%) presented symptoms between ID levels 2 and 4, and 122 (27.0%) could be classified as 'psychiatric cases' (ID levels 5-8). For this latter group, it is appropriate to use the CATEGO programme to make clinical diagnosis (Wing *et al*, 1974). Table III shows the diagnoses found for this sample in each level of GHQ score. Because the population investigated in the second stage was not a true probability sample, the prevalence frequencies had to be adjusted according to the probability of selection. The total weighted prevalence found in this sample was 14.7%, in which, female rates are substantially above the male rates (male=8.11%; female=20.58%).

TABLE I
Distribution of GHQ scores in the two-stage sample

GHQ Score	First stage			Second stage		
	Male	Female	Total	Male	Female	Total
12+	68	159	227	68	151	219
6-11	85	136	221	16	31	47
0-5	428	347	775	93	93	186
Total	581	642	1223	177	275	452

		Female	0	0	3	0.49	
	Total Morbidity	Male	2	3	22	8.11	14.74*
		Female	7	4	84	20.58	

*Total prevalence.

These morbidity figures are mainly accounted for by depressive and anxiety symptomatology. It was apparent that in this community, women tended to develop more anxiety and men more depression.

Validation analysis of the GHQ

In view of the fact that the PSE-ID system appears to produce a higher threshold for case identification than the Clinical Interview Schedule, which was the one used in the Spanish original validity study of the GHQ (Muñoz *et al.*, 1978), it seemed pertinent to test the performance of the GHQ on different cut-off points. Table IV shows the number of subjects according to whether they were defined as 'normal' or 'psychiatric case' on the 4/5 ID threshold score, and on different cut-off points for the GHQ. The statistics derived for males and females using these scores are in Table V; with a cut-off value of 11/12, the sensitivity for both sexes is superior to 80%, while the specificity drops, especially in women, below 70%. Accordingly, while the negative predictive value reaches very high

figures in both sexes the positive predictive rates are, especially in males, quite low. By raising the cut-off point in the GHQ to 19/20, it is possible to obtain a progressive reduction of the overall misclassification rate, together with significant rises of the positive predictive values. At this maximum cut-off point, the negative predictive value is still agreeably high. This improvement of the efficiency of the GHQ when the cut-off point is raised to 19/20 is achieved at the expense of decreased sensitivity and increased false negative rates. The differences which appear in these rates between the two sexes are not statistically significant.

There is a widespread opinion that the criteria used for case identification on the PSE are far more stringent than those applied with the CIS. This implies that we would classify as 'normal' those whose symptoms would have been sufficient to be included as cases in the original validity studies. If this were so, one would expect that by lowering the threshold of normality on the PSE-ID system to 3/4 (ID level: 1-3 = 'non case'; 4-8 = 'case'), we would improve the validity of the GHQ. Table VI shows that by

TABLE IV
GHQ scores for different cut-off points related to psychiatric assessment by the PSE-ID system

GHQ Score		Male (n = 178)		Female (n = 274)		Total Sample (n = 452)

	'Normal' (ID=1-3) n = 133	'Case' (ID=4-8) n = 45	'Normal' (ID=1-3) n = 146	'Case' (ID=4-8) n = 128	'Normal' (ID=1-3) n = 279	'Case' (ID=4-8) n = 173
'High score' (GHQ = 12-60)	32	35	46	107	78	142
'Low score' (GHQ = 0-11)	101	10	100	21	201	31
Sensitivity		77.8		83.6		82.1
Specificity		75.9		68.5		72.0
Positive predictive value		52.3		69.9		64.6
Negative predictive value		90.9		82.6		86.6
Misclassification rate		23.6		24.5		24.1

doing this, it is possible to increase the specificity to 72.0% and the positive predictive value to 64.6%, without making the sensitivity and negative predictive rates much worse. These variations of the validity statistics are apparent in both sexes.

The correlation between GHQ scores and PSE-ID ratings was 0.61 using Spearman's rank correlation. Males exhibited a slightly lower correlation coefficient than females (male: 0.56; female: 0.61). Other socio-demographic factors such as age, marital status, social

TABLE VIII
Validity statistics of two new scoring systems (CGHQ₁; CGHQ₂) on different cut-off points

Scoring system	Cut-off point	Sensitivity	Specificity	Mis-classification Rate
CGHQ ₁	27/28	79.5	68.5	28.5
	29/30	74.6	73.0	26.5
CGHQ ₂	68/69	82.8	71.2	25.7
	73/74	77.9	74.2	24.8

class, educational level, or unemployment did not significantly influence the validity statistics of the GHQ.

Analysis of new scoring systems for the GHQ

In an attempt to overcome the reported inadequacy of the GHQ to detect chronic neurotic illness Goodchild & Duncan-Jones (1985) proposed two new scoring systems (CGHQ₁ and CGHQ₂). These revised systems are based on the assumption that the response 'no more than usual' to items describing a symptom might indicate chronic illness, although conventionally it would be scored as healthy. They differentiated a set of items describing pathology ('N-Items') from others describing positive or healthy states ('P-Items'). On the GHQ-60, these two sets of items are composed by: 'P-Items': 1, 7, 15, 16, 21, 26, 27, 28, 30, 31, 32, 33, 35, 37, 42, 46, 53, 54; 'N-Items' the 42 remaining items.

On the different scoring systems, the four response categories for each item of the 'N-Items' and 'P-Items' sub-sets are scored according to the rules describe in Table VII.

Table VIII shows the validity statistics of the new scoring on different cut-off points. The cut-off scores where the validity indices are most nearly equal are, for the CGHQ₁ 29/30, and for the CGHQ₂ 73/74. The validity indices derived in this way are almost equivalent to the ones obtained with the conventional GHQ scoring at the level 13/14. In view of the relevance of reaching a higher sensitivity ratio, for epidemiological purposes, the cut-off points for these revised systems could alternatively be placed at the levels 27/28 (CGHQ₁) and 68/69 (CGHQ₂) for a two-stage community survey. The validity statistics derived from these cut-off scores are comparable to those obtained from the conventional GHQ scoring at the level 11/12. The similarity of the screening efficiency of the GHQ on these scoring systems is confirmed by Spearman's rank correlation of the GHQ score on each of the three systems with the PSE-ID score (PSE-GHQ=0.61; PSE-CGHQ₁=0.52; PSE-CGHQ₂=0.59). It appears, therefore, that the proposed modifications of the GHQ scoring systems do not significantly improve the detection of psychiatric morbidity in our data base.

False positives (GHQ cut-off score 11/12, PSE-ID threshold score 4/5)

In this study, 114 persons (46 male and 68 female) were classified as 'false positive' and it is relevant to try to identify the factors that contribute to this status by comparing 'false positive' with 'true negative'. This applies to comparisons of age distribution, sexual differences, marital status, work situation, and presence of physical complaints. We found more false positives in the widowed ($X^2=11.3$; $df=1$; $P<0.001$), in older ages (false positive: mean age=52.0; $SD=18.3$; true negative: mean age=46.9; $SD=18.5$; $t=2.39$; $P<0.05$) in persons out of work ($X^2=7.4$; $df=1$; $P<0.001$) and with higher mean levels of physical complaints ($t=11.70$; $P<0.001$).

To test whether the time interval between the GHQ and the PSE could contribute to these high figures of 'false positives', by allowing some transient symptomatology to be spontaneously resolved before the second stage interview, we compared the 'false positive' groups with the remaining validity groups in terms of their time intervals. The mean time interval between GHQ and PSE assessment for the 'true positive' group was 34.1 days ($SD=5.0$), which was significantly lower than that of the 'false positive' group ($\bar{X}=35.7$ days, $SD=5.44$; $t=2.26$; $P<0.01$). The mean time interval in the 'true negative' group was also significantly lower ($\bar{X}=33.24$ days, $SD=5.60$) than that of the 'false positive' ($t=3.87$; $P<0.001$), but this did not happen in the case of the 'false negative' group (time interval: $\bar{X}=34.2$ days, $SD=5.46$; $t=1.00$; NS). The significance of time interval differences held also good when 'false positives' were compared with the sum of the remaining groups 'remaining groups' time interval: $\bar{X}=33.52$ days, $SD=5.41$; $t=3.38$; $P<0.001$).

False negatives (GHQ cut-off score 11/12, PSE-ID threshold score 4/5)

Sixteen persons (five male, eleven female) were classified as 'false negatives'. As Table III shows, ten of these belonged to the diagnostic category of 'anxiety states', five to that of depression, and one to schizophrenia. Among the 'anxiety states' there was higher tendency, not statistically significant, to produce 'false negatives'. Earlier studies suggest that defensiveness and chronicity of psychiatric symptomatology are the most important factors in determining 'false negative' status. We found only three of our 'false negative' patients were afflicted by long-standing psychiatric symptomatology, while six patients were suffering from long standing physical complaints. We did not find any significant association between 'false negative' and social or demographic factors.

Discussion

The psychiatric morbidity found in this community was much lower than that previously found with a similar design in the Baztan valley (Vázquez-Barquero *et al*, 1981; 1982). Although there were evident sociological differences between these two rural Spanish communities, one could postulate that

these differences were mainly due to having used two different psychiatric interviews: the Clinical Interview Schedule in the Baztan valley and the Present State Examination in this community. This is also supported by the fact that our present figures are similar to the ones detected by other authors applying the PSE to quite different communities (Henderson *et al*, 1979; Bebbington *et al*, 1981).

We demonstrated in this study that contrary to what has been previously stated (Tarnopolsky *et al*, 1979; Benjamin *et al*, 1982), the GHQ is a valid instrument for screening possible cases in the initial step of a two-stage community survey. The good performance of the GHQ in this situation is demonstrated by the high sensitivity rate reached in this study (above 0.80 in all cases), which guarantees the ability of the GHQ not to miss possible psychiatric cases in the second stage.

However, unlike the sensitivity and false negative values, the specificity and false positive values are considerably poorer in this study. We applied the PSE as the external criterion of caseness, which is reputed to use a more stringent criterion for case identification than that used by the CIS. One should therefore expect that raising the cut-off point on the GHQ or lowering the threshold of 'caseness' on the PSE-ID, would have significantly reduced the proportion of 'high scorers' in the GHQ which were evaluated as 'non cases' on the PSE, and, to a certain extent, this happened. However, in spite of these manipulations of the thresholds, we are still left with high figures of 'undetected high scorers', suggesting that the relevant point here may not be the severity, but rather the quality, of the symptomatology. It therefore appears that the GHQ fails to distinguish between clinical states such as the ones classified as 'cases' or even 'specific psychiatric symptoms' by the PSE, and other types of psychiatric complaints. These psychiatric manifestations may be equivalent to what other authors have defined as 'transient distress symptoms' (Finlay-Jones & Murphy, 1979; Corser & Philips, 1978).

An additional methodological explanation for our high figures of 'undetected high scorers' is that the time which elapsed between the completion of the GHQ and the psychiatric interview could have allowed some transient psychiatric morbidity to resolve spontaneously and not be reported at the interview. There is support for this (Finlay-Jones & Murphy, 1979; Corser & Philips, 1978) and it is possible to suggest that the GHQ detects as 'cases' some individuals whose symptoms are very transient. The relevance of transient symptomatology in an untreated population has also been substantiated by Tennant *et al* (1981) in the second Camberwell

survey, in which it was shown that 49% of cases identified at a first interview were no longer cases a month later while we demonstrated that the 'false positive' rate is increased significantly by the time interval between GHQ and PSE assessment. This finding strengthens the conviction that transient disturbances are detected by the GHQ, and also throws some light on the impact of the time interval on the application of a two-stage design in a community survey.

Shrout & Fleiss (1981) stated that analysis of the performance of a screening test should not stop with its sensitivity and specificity since, we do not know who is truly a case and who is not. The rates that indicate the correctness of classification are the positive and negative predictive values, which depend not only on the validity coefficients of the test, but also on the prevalence of the disease in the population. The cut-off score where the GHQ reaches its maximum efficiency, as measured by these values, is the 19/20; at this level, we obtained a overall mis-classification rate of 19.7%, together with a reasonably balanced positive and negative predictive rates (68.1% and 83.4% respectively). Raising the threshold of caseness from 11/12 to 19/20, when using the GHQ-60 alongside the PSE-ID system, is convenient (Goldberg, 1981), but the gain we reported in the efficiency of the test was achieved at the expense of a considerable drop in the sensitivity rate. In order not to miss a high proportion of 'cases' in the second stage of a two stage community survey, we have to choose a lower cut-off score, and thus be prepared to tolerate a much worse positive predictive value.

Our findings show that contrary to previous reports (Tarnopolsky *et al.*, 1979; Hobbs *et al.*, 1984), sex differences do not introduce a significant degree of variation in the correlation coefficient between the GHQ and the PSE, and the same is true of the remaining validity figures. Since the performance of the GHQ is not significantly affected by the social background of the respondents, socio-demographic factors do not significantly influence the screening capacity of the GHQ in the community.

False positive status was characterised by a predominance of females, widowed marital state, old age, unemployment, and higher levels of physi-

cal complaints. This tendency of false positives to congregate among distressed persons with adverse life events or physical illness is in agreement with the findings of Finlay-Jones & Murphy (1979) and of Corser & Philips (1978); it raises again these authors' reservation about the ability of the GHQ to distinguish psychiatric disorders from transient states of distress.

When the GHQ is used to screen for possible cases in the initial step of a two-stage design, the most relevant quality is the ability to minimize false negatives, because they represent cases that are lost for the survey. Contrary to those of Benjamin *et al.* (1982), our results demonstrate that this is not an important source of bias in the community. It has been said repeatedly that the most important factor in determining false negative status is, at least in consulting settings, the chronicity of psychiatric symptoms, but our results, although inconclusive, support the opinion of Goldberg (1978) that this is not an important source of misclassification in the community.

Greater weight is provided to chronicity in the new GHQ (CGHQ₁; CGHQ₂) scoring systems (Goodchild & Duncan-Jones, 1985). This revised scoring provides better prediction of morbidity than the conventional GHQ scoring, and advocates suggest that it be adopted for epidemiological research, but its use did not improve the screening capacity of the GHQ in our data. This may be because the aim of the new system is to give a more accurate reflection of chronic symptomatology and not of 'transient states of distress', which were the sort of conditions which appeared to provoke the higher percentage of mis-classification in our study, whether these new scoring systems improve screening in clinical settings should be tested in an appropriate study.

Body Size Estimation in Bulimia

ANDREW M. WHITEHOUSE, CHRISTOPHER L. FREEMAN and ANNETTE ANNANDALE

Body size estimation was studied in 22 patients with bulimia and 20 normal controls. Two methods of body size estimation were used, a distorting television image method (DTIM) and the image marking method (IMM). The subjects estimated body size of a dummy as well as their own body on the DTIM. When estimating body size on the DTIM the bulimics overestimated and the controls underestimated, there being a significant difference between the two groups. There was no difference between the groups when estimating the size of the dummy. On the IMM a significant difference was found between the bulimic and control groups, the bulimics overestimating body size and the controls being more accurate. Marked directional effects were found with the DTIM. The two methods of body size estimation are compared.

Bulimia is an eating disorder which has been operationally defined in DSM-III (APA 1980). The clinical features described in the DSM-III diagnostic criteria include recurrent episodes of binge eating, severely restrictive diets, self-induced vomiting and abuse of laxatives or diuretics. The patient experiences depressed mood following eating binges and is aware that the eating pattern is abnormal. If the bulimic episodes are due to anorexia nervosa the patient would be excluded from a DSM-III diagnosis of bulimia. Bulimia nervosa was described by Russell (1979) as a later sequel of anorexia nervosa. More recently he has stated "in 'true' bulimia nervosa there is a history of a previous episode of anorexia nervosa, possibly of minor severity" (Russell, 1985). Bulimia nervosa is generally considered a disorder of greater severity than DSM-III bulimia.

There have been numerous studies of body size estimation in anorexia nervosa prompted by Bruch's (1962) proposal of a disturbance of body image in the condition. Methods used to examine body size estimation can be divided into those that measure 'body part' estimation such as Slade and Russell's (1973) visual size-estimation apparatus and 'whole body' methods such as the distorting photograph method (Garner *et al.* 1976). Studies measuring 'body part' estimation have found an overestimation of body size in anorexia nervosa (Slade & Russell 1973, Button *et al.* 1977, Pierloot & Houben 1978, Crisp & Kalucy 1974, Garner *et al.* 1976, Casper *et al.* 1979, Fries 1977). However, most studies have found a similar degree of overestimation amongst controls. Using a 'whole body' method Garner *et al.* (1976) found that controls

underestimated body size, whereas anorexics produced a mean score near the non-distortion position, the difference being significant. More recently Touyz *et al.* (1984a) using a similar method also found anorexics to be on average accurate in estimating body size, there being no difference from controls.

Bulimics have abnormal attitudes towards food, eating and body weight in common with patients with anorexia nervosa. Body image disturbance has also been described clinically in bulimia nervosa with virtually all patients in one series reporting feeling persistently fat (Fairburn & Cooper 1982). Body size estimation in bulimia has been examined by Freeman *et al.* (1984) using a modified video camera technique. Significant differences were found between bulimic and control groups, with patients with bulimia nervosa overestimating body size. This study examines body size perception of patients with bulimia using both 'whole body' and 'body part' methods as the two methods have produced different results in body size estimation in anorexia nervosa. The 'whole body' method used was a distorting television image method (DTIM), similar to that described by Allebeck *et al.* (1976). It is essentially the same as the technique used by Freeman *et al.* (1984), the only difference being the equipment used and the degree of distortion of body size achieved. It has been shown to be a reliable procedure with an internal consistency coefficient of 0.62 (comparing frontal and profile body image scores) and a high test, retest reliability ($r=0.90$). The 'body part' method used was the image marking method (IMM) introduced by Askevold (1975), which has an internal consistency coefficient of 0.60 (Garner & Garfinkel 1983).

Method

Subjects

The experimental group consisted of 22 patients with bulimia, all fulfilling DSM-III criteria. Of these, 20 also fulfilled Russell's criteria for bulimia nervosa. Twenty-one were out-patients consecutively referred to the Edinburgh Eating Disorders Clinic at the beginning of their treatment and one was an in-patient. Nine patients were referred by their general practitioner, four by a psychiatrist or psychologist and one by a self-help group; Eight were self-referred. The control group comprised of 20 subjects who were trainee medical and paramedical staff. It was decided that control subjects who were 25% underweight or overweight would be excluded for these reasons.

All subjects completed the Eating Disorder Inventory (EDI) produced by Garner *et al* (1983). The subjects were required to wear a medium blue leotard for both methods of body size estimation. While it was inevitable that all subjects were aware that body size estimation was being measured the subjects were not aware of the aims of the study or the findings up to that point in time.

The Distorting Television Image Method (DTIM)

The apparatus is illustrated schematically in Figure 1. The subject stood 5 metres from a National WV.341N video camera (focal length of lens=75 cm) against a neutral background, and illuminated with a video light.

They were able to view an image of themselves on a black-and-white television monitor to their left. The conductor (AW or AA) could narrow or widen the television image electronically, using control apparatus which varies the voltage across the horizontal and vertical axis of the television monitor. The vertical control was set so as to achieve a 50% degree of distortion in a positive or negative direction on the horizontal axis. The conductor could view the distorted image on a second monitor to ensure a smooth change of distortion, and could read the voltage on the horizontal axis from a voltmeter with a digital read out. The system had previously been calibrated producing a graph of voltage against degree of distortion. The degree of distortion of the image could therefore be obtained from this graph using the voltage results.

The conductor adjusted the television picture to its narrowest and gradually widened it. The subject stopped the conductor verbally when they felt that the image was a correct reproduction of themselves. The television picture was then set to its widest and gradually narrowed, the subject again indicating when the image was accurate. This was necessary as the pilot study had shown marked directional effects, that is when the image was initially narrow the subject tended to reproduce a narrow image and when initially wide the subject tended to reproduce a wide image. The two trials were repeated and the scores averaged to give a composite score. The video camera was next focused on the subject's face and exactly the same procedure was carried out. A white shop window dummy was then placed in front of the video camera, on the spot the subject had

Fig. 1 Illustration of distorting television image apparatus.

been standing. The subject was then required to examine the dummy for 20 seconds and was asked to indicate the correct reproduction of the dummy on the monitor, again over four trials.

The Image Marking Method (IMM)

This method is described in detail by Askevold (1975). The subject stands at arm's length from a white board. They are asked to imagine standing before a mirror, looking at themselves. The investigator stood behind the subject and touched body points on the subject's shoulders, waist and hips. The subject marked on the board where they felt these points would be in the imaginary mirror. The actual widths were then recorded.

Results

The mean age of the patients with bulimia was 24.9 years (s.d.=6.2); their mean weight on assessment was 61.3 kg (S.D.=13.5) or 105.4% (s.d.=19.1) of average weight for height (Documenta Geigy 1962). The mean lowest past adult weight for the bulimics was 52.9 kg (s.d.=9.2)

TABLE I
Clinical features and their frequency in the bulimics (n = 22)

<i>Clinical features</i>	<i>%</i>
Bulimia	100
More than 3/day	5
2-3/day	18
daily	32
More than 1/week	36
1/week	9
Self-induced vomiting	73
2-3/day	27
daily	23
2-3/week	18
monthly	5
Laxative abuse	50

and the mean highest past adult weight was 69.3 kg (s.d. = 14.2). The clinical features of the 22 bulimic patients are shown in Table I. The mean age of the control group was 25.4 years (s.d. = 5.1); their mean weight was 56.5 kg (s.d. = 5.8) or 99.4% (s.d. = 8.7) of average weight for height and age. The bulimics had a significantly higher score than controls on the following EDI subscales; Drive for Thinness, Bulimia, Body Dissatisfaction, Ineffectiveness, Perfectionism, Interpersonal Distrust and Interoceptive Awareness. There was no significant difference between the groups on the Maturity Fears subscale. Body size estimation was calculated according to the formula of Slade and Russell (1973):

$$\text{Body Perception Index (BPI)} = \frac{\text{average perceived size}}{\text{actual size}} \times 100$$

The results of the DTIM are shown in Table II. The BPI is presented separately for measurements taken when the image was initially narrow and initially wide, because there were such marked directional effects. These two scores are combined to give a composite score. If the composite scores are examined first it can be seen that when estimating the size of the dummy, the groups are equally inaccurate. However, when estimating the size of their own body, the bulimics overestimate body size, with the controls showing an underestimation. When estimating the size of their face the bulimics again show an overestimation with the controls being fairly accurate. The raw data of the whole body composite scores gives a more comprehensive picture and is shown in Figure 2. There is only one control with a BPI score of 105 or greater, whereas this is the case for 10 of the bulimics (45%), a significant difference ($\chi^2 = 6.90$ $P < 0.01$). There is a large overlap of scores between the bulimics and the controls with 27% of the bulimics underestimating body size.

When the BPI results presented separately in Table II are examined, marked directional effects are seen in both groups when estimating the size of the whole body, face and dummy. For example the whole body BPI results for the bulimics for the two directions are 90.4 and 115.7 which are significantly different ($t = 7.57$ $P < 0.001$). The whole BPI results of the controls for the two directions are 86.3 and 105.9 which are again significantly different ($t = 7.75$ $P < 0.001$). It should be noted that the difference in whole body BPI results between the bulimics and the controls is only significant when the image was initially wide. The same situation is encountered when looking at the BPI scores for the face. The difference between the groups is again only significant when the initial image presented was wide.

The results of the IMM are shown in Table III. Both groups underestimated the size of their shoulders. The bulimics overestimated waist size with the controls being accurate. Both groups overestimated the size of their hips,

Fig 2 Body perception indices (whole body) with the distorting television image method.

Fig 3 Body perception indices (composite score) with the image marking method.

TABLE III
Body Perception Index of the bulimics (n=22) and normal controls (n=20) with the Image Marking Method

	<i>Bulimics</i>	<i>SD</i>	<i>Controls</i>	<i>SD</i>	<i>t test values</i>	
Shoulders	97.7	12.3	94.3	11.6	0.9	NS
Waist	111.2	17.5	99.0	14.6	2.07	P 0.05
Hips	123.4	23.2	111.2	12.6	2.16	P 0.05
Composite score	110.8	15.5	102.2	10.9	2.10	P 0.05

with the degree of overestimation being significantly greater in the bulimic group. When the shoulder, waist and hip size estimation are averaged a composite score is obtained for the whole body, with the bulimics overestimating body size and the controls being more accurate. The individual composite scores are presented in Figure 3. Only one control had a BPI score of 115 or more, whereas

this was the case for nine (41%) of the bulimics ($\chi^2 = 5.60$ $P < 0.02$). There is a large overlap of scores between the bulimics and controls with 27% of the bulimics underestimating body size.

If we compare the whole body BPI scores on the DTIM with the composite score of the IMM we find that for the groups combined they score 6.9 percentage points higher

on the BPI when tested on the IMM ($t=2.71$ $P<0.01$) There is no significant correlation between the BPI results for the two methods amongst controls ($r=+0.07$, $t=0.29$ NS), but there is a significant positive correlation amongst bulimics ($r=+0.44$, $t=2.19$ $P<0.05$) Rank-order correlations between severity of bulimia and body size estimation were examined. Severity of bulimia was based on frequency of binge eating. Where this was equal amongst individuals, frequency of self-induced vomiting was examined Kendall's rank correlation coefficient was used. There was no significant correlation between severity and BPI on the DTIM ($\tau=-0.024$ NS) or between severity and BPI on the IMM ($\tau=+0.03$ NS) There was a significant correlation between Body Dissatisfaction subscale score on the EDI and the BPI on the DTIM for the bulimics ($r=+0.64$, $t=3.72$ $P<0.001$) but not for the controls ($r=+0.39$, $t=1.79$ NS). No significant correlation was found between the Body Dissatisfaction subscale score and the BPI on the IMM for bulimics ($r=+0.03$, $t=0.13$ NS) or controls ($r=+0.01$, $t=0.04$ NS).

Discussion

The results of this study confirm those of Freeman *et al* (1983) in finding a significant difference between bulimic and control groups in estimating body size with the DTIM. This was not a general perceptual disorder of the bulimic patients as they did not differ from controls in estimating the size of a dummy. A significant difference was also found between the bulimic and control groups in estimating body size using the IMM. Bulimics had therefore been shown to overestimate body size with a 'whole body' method (the DTIM) and a 'body part' method (the IMM).

The very large directional effects that were found with the DTIM are difficult to explain. Subjects are clearly strongly influenced by the initial image they are shown. Previous studies have not presented data separately in this way. Our study suggests that such detail may be extremely important. The study by Freeman *et al* (1983) found a BPI for bulimics of 107.4 compared to 103.1 in this study. Furthermore, the controls in that study had a BPI score of 103.4 compared to 96.1 in our study. In view of the marked directional effects shown, it would seem that the major reason to account for the difference between the studies is the degree of distortion achieved with each method. Freeman *et al* achieved distortions of up to 20% 'thinner' and 40% 'fatter' whereas this study was able to achieve distortions of 50% in both directions. The initial images presented to subjects in the Freeman study were biased towards the 'fatter' direction and consequently BPI scores were higher. These directional effects are

also likely to be operating in other methods of estimating body size such as the distorting photograph method (Garner *et al* 1976) and the visual size estimation apparatus (Slade & Russell 1973). In future, research workers using these methods should present data separately so that directional effects can be examined.

With separate presentation of the data it can also be seen that the difference in whole body BPI scores between the bulimic and control groups is only significant when the initial image was wide. This is also true for the difference in face BPI scores between the groups. When the bulimics are presented a 'fatter' image of their body or face they are more likely to confirm that image than are controls. This effect would not be noted if only a composite score was given and again this is likely to be of relevance in other studies.

When the DTIM a 'whole body' method is compared with the IMM a 'body part' method, it is found that the combined groups have a significantly higher BPI on the IMM. This is in keeping with studies of body size estimation in anorexia nervosa, where 'body part' methods have found anorexics to overestimate body size, whereas 'whole body' methods have not found this. This means that estimation of body size is very much influenced by the method by which it is measured which should not be surprising in view of the directional effects found within the DTIM.

The BPI scores on the DTIM showed no correlation with those of the IMM for the controls though there was a significant positive correlation amongst the bulimics. This is a similar result to that of Garner *et al* (1976) who found that the visual size-estimation method (a 'body part' method) did not correlate with the distorting photograph method (a 'whole body' method) for controls but amongst anorexics and the obese there was a significant positive correlation. Clearly subjects with eating disorders who overestimate body size with a 'whole body' method do so with 'body part' methods as well. However, it becomes difficult to argue that such overestimation represents a distorted body image because if both these methods are measuring a subject's 'body image' then you would expect to find a significant positive correlation between the two methods amongst the controls.

Hsu (1982) has argued that overestimation of body size in anorexia nervosa does not necessarily indicate a disturbed body image but may reflect some other aspect of psychopathology associated with eating disorders such as fatness phobia. It could therefore be argued that the bulimic subjects in this study expressed the way they felt about their

body by overestimating body size, without having to invoke the term 'body image'. The fact that the BPI scores on the DTIM correlate significantly with the Body Dissatisfaction subscale of the EDI would lend support to this view.

An alternative explanation for the lack of correlation of BPI scores for the two methods amongst controls could be that each method is measuring a different aspect of body image. Slade (1984) has proposed that 'whole body' methods may measure a relatively fixed cognitive attitude to body size, and 'body part' methods measure a more fluid state of body size sensitivity strongly influenced by affective and emotional factors. Longitudinal studies utilising both types of body size estimation methods would be needed to confirm this.

It would seem that the concept of 'body image' is not at present a clear one. Light may be shed on this area by Touyz *et al* (1984b) who differentiate between how a subject feels they look and how they actually see themselves when estimating body size. This distinction may prove to be of help in our understanding of the term 'body image'. At the moment, it would seem preferable to use the more easily defined term of 'body size estimation' than 'measurement of body image' when describing methods which simply measure a subjects estimation of their own body size.

Control of Auditory Hallucinations through Occlusion of Monaural Auditory Input

MAX BIRCHWOOD

A schizophrenic patient whose severe level of auditory hallucinations had proved refractory to neuroleptic medication was given two treatment techniques derived from Green's theory that hallucinations represent verbal activity in the non-dominant hemisphere. Voice activity was markedly reduced in frequency and severity over a six-month period, and led to general improvements in interpersonal functioning. There was evidence for independent and additive effects of the two techniques

In spite of the therapeutic advances from the neuroleptic drugs, the persistence of auditory hallucinations remains a significant problem for both acute and chronic schizophrenic patients (Falloon & Talbot, 1981). Apart from the distressing nature of the experience itself, there is evidence that such symptoms may depress social functioning and in some cases underpin the formation of delusions (Wallace, 1984). There have been a number of reports of attempts to control hallucinations by behavioural strategies; but the results have been variable, and not firmly based on theory (Marzillier & Birchwood 1981).

Green *et al* (1983) suggested that auditory hallucinations represent verbal activity originating in the non-dominant cerebral hemisphere, and that the dominant hemisphere perceives this verbal activity as alien, due to a primary disassociation in the functioning of the cerebral hemispheres in schizophrenia. Green (1978, Green *et al*, 1983) reported evidence suggestive of poor inter-hemispheric transfer of complex manual and auditory information, which has been independently replicated (Carr, 1980; Hatta *et al*, 1984): this may not be a secondary (e.g. drug-induced) phenomenon (Myslobodsky *et al*, 1983), as similar results have been found in high-risk samples (Hallett & Green, 1983). Green's theory is consistent with previous observations of subvocal speech and movements of vocal musculature, concomitant with reports of "voices" (Erickson & Gustafson, 1968; Gould, 1948; Inouye & Shimizo 1970; McGugan, 1966). Green & Preston (1980) report that the content of (amplified) subvocal speech in one schizophrenic corresponded to the patient's self-reports of his voices, which were Schneiderian in character.

One prediction which stems from this theory is that if auditory input to the non-dominant hemisphere is reduced, and incompatible (dominant

hemisphere) verbalisations encouraged at the onset of the hallucinations, the voices may be disrupted. A further report (Green *et al*, 1980) records the success of this technique where auditory input is reduced using an ear-plug and the patient is taught to name things in his immediate environment at the onset of the voices; the choice of side for the ear-plug is determined by the results of an auditory comprehension (transfer) test. James (1983) has reported two cases where these techniques were used with apparent success; however, reversing the side of the ear-plug had no effect on voice reduction, which he regarded as evidence against the efficacy of the plug and as inconsistent with Green's theory. However, both techniques were employed simultaneously, so that while the side of the ear-plug was reversed, the subjects continued to use the naming technique; this confounding does not enable any effect of the ear-plug to be distinguished from the other voice control technique. More importantly, James employed an ear-plug when there was no indication from the auditory comprehension test to do so.

This paper reports a case where the effect of occluding auditory input to one ear was examined directly, in the case of a severely hallucinating schizophrenic patient.

Method

The subject

The subject was a 37 year-old male, with a two-year history of schizophrenia. At the height of the acute episode, his voices appeared to him to control everything he did or said, and to be capable of predicting his future; they instructed him to do irrational and bizarre things, which he felt he had to comply with. Following in-patient treatment, his overall presentation became more rational, and he reported that he had regained control over his thoughts

and behaviour. Following discharge he was maintained on neuroleptics (clopixol, 400 mg, fortnightly; orphenadrine, 50 mg t.d.s. and pimozide, 4 mg nightly). He lived in lodgings, and attended a work unit as a day patient, but still had continuous and severe hallucinations. His voices occurred at a very high frequency, were brief but highly repetitive in nature, and were perceived in a high-pitched male voice; they addressed him in the third person. His insight was fragmentary, and he sometimes believed the voices came from a previous life; he found the voices very distressing, and frequently shouted back at them. They occurred independently of any event or activity, but he volunteered the information that talking aloud seemed to suppress them.

Assessment

Green's Auditory Comprehension Test (Green, 1984) consists of a number of short stories of varying length and complexity, delivered under monaural or binaural listening conditions; the measure of comprehension is the number of items correctly recalled. The present subject's results were: right ear—60 items correct; left ear—35 items correct; both ears—63 items correct.

This indicates a significant left ear deficit in language comprehension, consistent with previous research results, and suggests a deficit in hemispheric integration (Green *et al.*, 1983). However, a binaural deficit did not emerge. Pure-tone audiometry indicated no hearing loss in either ear.

Intervention and Results

The subject was provided with a hand-held counter, which he was instructed to depress at the onset of each discrete episode of voice activity. Baseline recordings were taken for 28 days, and indicated a mean of approximately 310 episodes of voice activity per day (equivalent to one episode per three minutes). A sponge-type sound occluding ear-plug was then placed into the left ear, with no expectation given to the subject about its purpose. The results are shown in the figure.

There was a 46% drop in voice activity in the first week, compared with the last week of the baseline period; 12 days following this intervention, the second technique derived from Green's theory was employed. The patient was instructed to say 'Stop', and to name things in his immediate environment, with the emphasis being on loudness and speed of naming. During the 12 days in which the subject wore the ear-plug, there was a slow rise from 140 to 210 episodes of voice activity per day. On the introduction of the second technique, this rise was apparently 'checked', although the possibility that this simply represented spontaneous fluctuations in the record cannot be ruled out. There was a slow improvement over the following 84 days. The recording was suspended and the patient followed up 44 days later, and 24 further days of recordings were taken, showing evidence of a further moderate decline. To test the specific effect of the ear-plug, the subject was now requested to remove it, whilst continuing with the 'stop

FIG. The effect of the treatment techniques on hallucinatory activity

and name' technique, but after four days of daily monitoring, it was decided to re-introduce the plug, as the patient reported feeling disturbed by the voices. (Further experimental manipulations of the techniques were not attempted for this reason). The removal of the plug had given rise to a 25% increase in voice activity (see Figure). Concomitant with the decline in self-reported voice activity, the patient also commented on a reduction in their audibility, and further validation of the patient's improvement came from ward staff, who commented that he appeared much more animated and talkative.

Discussion

The results show clearly that the effect of occluding auditory input to the (presumably) non-dominant hemisphere was markedly to reduce the frequency and severity of voices in this severely hallucinated schizophrenic patient. The efficacy of incompatible dominant hemisphere verbalisations (the 'stop and name' technique) was less certain, as experimental manipulations of this technique could not be attempted, but two observations suggest that this technique did have an independent effect. Firstly, a rise of 70 episodes of voice activity per day, over the 12 days during which the ear-plug was employed, was discontinued on introduction of (the 'stop and name' technique) though this could be accounted for by 'spontaneous' fluctuations in the record. Secondly, during the experimental withdrawal of the ear-plug over four days the rise in voice activity did not return to baseline, and this was possibly accounted for by the continued use of this technique. However, it is possible that the techniques had actually led to a reduction in the level of the baseline, in which case this conclusion would have to be tempered. Only complete withdrawal of both techniques would establish this.

The results are consistent with an independent effect of 'stop and name' and an additive one with the ear-plug, but the data are inconclusive on this point. Variants of these two techniques have in fact been independently reported. Falloon & Talbot's (1981) study of schizophrenics' self-reported coping strategies revealed that reduced attention to voices, particularly where this involves the evocation of alternative thoughts or verbalisations, appeared to be a helpful tactic. Incompatible verbalisations were employed in a successful single case study (Erickson & Gustafson, 1968)—a feature common to many other successful single-cases (Marzillier & Birchwood, 1981). McGuffin (1979) reports the case of a young disturbed schizophrenic patient who of his own accord, wore ear-plugs "to hear things clear": this also led to an improvement in his general sense of well being and interpersonal functioning (similar in fact to the present case). He also mentions two further cases of hallucinated patients who showed improvement with ear-plugs.

Many of the subjects of Green *et al* (1983) showed a binaural deficit in comprehension, compared with the "best" ear—a phenomenon not observed in the present subject. One is tempted to speculate that in such a severely hallucinated patient there may be somewhat more profound hemisphere disassociation, thereby reducing interhemispheric inter-

ference, which Green suggests accounts for the binaural deficit. Gazzaniga *et al* (1979) reported the case of a split-brain patient, where the non-dominant hemisphere seemingly developed expressive and intrusive speech. There is, however, another theory of auditory hallucinations within the cerebral laterality literature, which is consistent with the treatment findings. This idea, espoused by Flor-Henry (1976), argues that this and other psychotic phenomena occur as a result of disorganisation in the dominant orbital temporal-frontal regions. Flor-Henry draws parallels between the hallucinations sometimes observed in temporal lobe epilepsy and those of schizophrenia. However, if the present subject had such an impairment, one might have anticipated no ear differences in language comprehension if the functions of the primary language areas were disturbed.

The present results, together with those reported by Green and James, suggest the need for further research to establish the generality and specificity of the theory and of the relevant voice-control techniques.

(Accepted 22 May 1985)

Obsessional Symptomatology and Adverse Mood States*

BASEM T. FARID

Patients suffering from obsessional neurosis without other psychiatric diagnosis were examined with reference to the association of the mood disorders of depression, anxiety, and outwardly and inwardly directed irritability. All mood disorders were common, and many occurred together in individual patients, but anxiety was the most prevalent. Inwardly directed irritability was significantly related to the overall severity of obsessions, and to the degree of handicap or interference in everyday life experienced by the patient.

The relationship of obsessional neurosis to disorders of mood has been the subject of intensive enquiries over many years. Sometimes, reports of associations have appeared to be objective, but at other times objectivity has been submerged by the need to provide support for a preconceived theoretical standpoint. The literature has been reviewed by Snaith (1981a) and by Farid (1983); only its salient features will be presented here. Although the mood disorders of depression, anxiety, and irritability are usually inextricably intermingled, the present report deals with them as separate states.

Depression: The observation of the association between depressive illness and obsessional symptoms commences with the study of Lewis (1934), in which 21% of severe melancholics had obsessional symptoms; Stengel (1945) considered that cyclical depressive illness could present with such prominent obsessional symptoms that the underlying nature of the disorder was obscured. Kringlen (1965) noted the association between obsessional neurosis and depressive symptoms; Kendell & Discipio (1970) found a greater than chance association between obsessions and depression, and Coryell (1981) confirmed an association between the two disorders. The relationship between obsessional symptoms and an underlying disorder of mood has been examined in a series of papers by Beech (e.g. 1971); an underlying mood disorder appeared to be a primary event in a chain culminating in obsessional behaviour, and the mood disorder was characterised by depression and irritability rather than anxiety. Miller (1980) found that obsessional patients showed a marked negative cognitive set rather than true depression, and speculated that obsessional symptoms are coping devices which defend against depression.

Anxiety: The relationship between obsessional symptoms and anxiety is a central theme for those who examine the concepts from a behavioural standpoint. Lorr & Rubinstein (1956) found a significant association between obsessional symptoms and an anxiety-tension factor. Rachman (1971) considered that obsessional ruminations arise in the context of altered mood states and that attempts to escape the ruminations by neutralising thoughts reduce anxiety only temporarily, the relief leading to further positive reinforcement of the disorder. Beech (1978) postulated that there is a defect of the arousal system, so that minor alterations to the incoming stimulation precipitate major defensive reactions, leading to anxiety.

Irritability: This term is widely used but rarely defined. Until recently, the *Index Medicus* had no Medical Subject Heading for irritability, and all works relating to the concept had to be classified under the heading either of aggression or hostility, but from 1985, Irritable Mood is to be included as a Medical Subject Heading (Snaith & Taylor, 1985). The literature on the relationship of this mood disorder to obsession is not very extensive, and it is not always possible to be sure that the terms have been used in the same sense. Fernando (1977) found a relationship between obsessional symptoms and aspects of hostility, while Mellett (1974) detected an unusual inclination among obsessional patients to suppress anger. In another study (Manchanda *et al.*, 1979), there was a significant difference between obsessionals and a matched control group of neurotic depressives in relation to hostility, the obsessionals showing greater acting-out hostility and extra-punitive tendencies; Miller (1983) has confirmed a relationship between hostility and obsessional neurosis.

*Based on a dissertation for the degree of M.Med.Sc. University of Leeds and which was awarded the Max Hamilton Prize.

The present study aimed to examine the relationship between aspects of obsessions and disorders of mood, in a group of patients suffering from severe disabling obsessional neurosis, who accord to a strict definition of obsessional neurosis (Feighner *et al.*, 1972) and who were not currently suffering from other major psychiatric disorder which might be considered to be the primary disorder or which would at least lead to a collateral classification in the International Classification of Diseases. Aspects of mood disorder (depression, anxiety, and irritability) were defined and assessed both at interview and by self-report. This report is a survey of associations, and no attempt has been made at a theoretical interpretation.

Method

The sample consisted of consecutive referrals to the author, who had notified his colleagues in two hospitals of his interest to study mood disorder in relation to obsessional neurosis. The criteria for the diagnosis of obsessional neurosis were those of Feighner *et al.* (1972); no patient was included whose primary diagnosis was considered not to be that of obsessional neurosis, but who manifested obsessional symptoms in the setting of some other psychiatric disorder. The purpose of the research was explained to the patients, and their consent obtained. The final sample consisted of 20 patients (17 females, three males), with a mean age of 36 years (range: 23–49). Many patients had suffered from the disorder for several years, and the mean age of onset was 21 years (range: 16–26). Patients and referring psychiatrists considered the neurosis severe enough to require psychiatric treatment. At the time of the interview, seven subjects were in hospital and the rest outpatients.

The following assessments were undertaken during the course of an interview lasting between one and two hours:

(i) *Leyton Obsessional Inventory* (LOI) (Cooper *et al.*, 1970). This produces an overall index of the number of obsessional traits and obsessional symptoms present; it also provides scores representing the degree to which the patient attempts to resist the obsessional symptoms (Resistance), and the degree to which the symptoms interfere with the daily life of the patients (Interference).

(ii) *The Clinical Interview* (CI), based on the Standardised Psychiatric Interview (Goldberg *et al.*, 1970). The measures relating to depression, anxiety, and irritability were extracted; each mood disorder is rated on a five-point (0–4) scale, and for the purpose of the present research, scores of 0 and 1 were taken to indicate an absence of the mood disorder, and of 2, 3 or 4 to indicate the presence of a moderate to very severe degree of the disorder. The definitions provided by the instrument were adhered to, except in the case of irritability. The manual states that irritability should be assessed not only according to the degree of irritability and impatience in relationship with others, but also according to the degree of personal sensitivity; this latter aspect was omitted in the present study, and the

ratings reflected the degree of the patients' own statements about poor control, or feelings of poor control over temper, leading to expressions of aggression or violence.

No rating as high as 4 was made in any patient, but ratings of 3 reflected severe arguments or actual, albeit mild, physical violence.

(iii) The Irritability-Depression-Anxiety (IDA) Scale (Snaith *et al.*, 1978). This self-completion scale provides separate sub-scales for: depression, anxiety, and two aspects of irritability: expressed towards others (outward irritability), and directed towards the self (inward irritability).

The patients' scores on the IDA scale were unknown to the author at the time of the clinical interview. There is a broad agreement between the first three sub-scales of the IDA and the appropriate Scales of the CI, but the inward-irritability sub-scale had no counterpart in the CI.

Results

The scores on the CI and the IDA Scale are given in Table I. Only scores representing abnormality of mood, i.e. 2 or 3 on the CI or above the borderline range for the sub-scales of the IDA, are recorded; abnormality appears on one or other dimension in 19 patients, although four patients had no abnormality of any score on the CI.

Strict criteria were used for the definition of the presence of a mood disorder—that an abnormality of mood should be present on both the CI and the self-assessment scale before being recorded as such; this is in accord with Snaith's (1981b) view that in investigations of this type, a combination of clinical and self-assessment has advantage over either method alone. However, since the inward irritability self-assessment scale had no counterpart in the CI, reliance had to be placed on that scale alone. The criteria for inclusion of an abnormality of mood were therefore raised from the score above the top of the borderline range to one in the upper third of the score range, i.e. 9 or higher. By these criteria, anxiety was present in 15 patients, depression in nine patients, outwardly directed irritability in five and inwardly directed irritability in eight. No disorder of mood was present in four patients, but disorder of all four mood states in four.

The next stage of analysis was to examine the presence or absence of mood disorder in relation to the variables of the LOI (Table II).

The only significant associations were between the two aspects of irritability and the total LOI Score, and between Inward Irritability and the Interference of obsessions in daily life. It was considered that this method was a meaningful way of presenting the findings, but rank correlations (Spearman) were also calculated, and these support the analysis.

The correlations which were statistically significant were: CI—Anxiety/LOI—Total, $r+0.46$, $P<0.05$; CI—Anxiety/LOI—Interference, $r+0.51$, $P<0.02$; IDA—Outward Irritability/LOI—Total, $r+0.52$, $P<0.02$, IDA—Inward Irritability/LOI—Total, $r+0.74$, $P<0.01$ and IDA—Inward Irritability/LOI—Interference, $r+0.61$, $P<0.02$. Thus, correlations over the total range of scores for each

Inward irritability	Present	8	47.0 (2.2)**	56.4 (6.1)*	45.0 (6.8)
	Absent	12	37.2 (2.4)	37.6 (4.0)	45.0 (6.8)

Mean, (Standard errors), significance of difference (t-test) only significance values of $P < 0.02$ or higher are considered. ** $P < 0.01$, * $P < 0.02$

mood disorder of the CI and sub-scales of the IDA, with each LOI variable showed a weak significant relationship between Clinical Anxiety and LOI Total and LOI Interference. However, the clinical assessment of irritability did not have significant correlations with any of the LOI variables, although the irritability sub-scales of the IDA did.

Discussion

This study confirms previous reports (*inter alia*, Orme, 1965; Walker & Beech, 1969; Vaughan, 1976) that depression, anxiety, and irritability are prevalent and inter-related in patients suffering from obsessional neurosis. The central finding is that irritability, as defined above, has a clearer relationship than other mood disorders with both the overall severity of the obsessional neurosis and the degree to which the patient considers that his symptoms interfere with daily life. A weakness of the study arises from the definition of overall severity and other aspects of the obsessional disorder, inherent in the use of the LOI. Its scores of severity are from the number of obsessional symptoms present, which would allow only low scores to be derived by a patient who suffers from a single obsessional symptom and yet is severely handicapped by it. Further studies should pay attention to this point, and also to the fact that at the time of assessment, patients in hospital may be less severely handicapped by obsessional symptoms than those assessed at home.

The finding that anxiety is the commonest associated mood disorder should be taken in context with the fact that patients suffering from primary depressive or anxiety states were excluded. Moreover, this finding should not be related to consideration of the relationship between anxiety provoked by, or associated with the individual obsessional symptom, since the concept used was that of pervasive disturbance of mood, rather than anxiety directly engendered by the obsessions. It is in the latter sense that Walker & Beech (1969) made their observations of the relationship between obsessions and mood. The finding that outwardly directed irritability is less commonly experienced than that inwardly directed may be a useful observation on which to base both further studies and clinical management. Inwardly directed irritability is found to be both common and related to the overall severity of the obsessional neurosis and to the degree of interference or handicap produced by the symptoms. However, this concept should not be too readily equated with that of suicidal propensity; two out of the four items of the IDA Scale, on which the concept is based, relate to thought of hurt or harm to the self (not necessarily with fatal result), and the other two items are less strongly expressed, referring to annoyance and angry feelings of the patient about his own state. It is in this sense of the second of these concepts that the finding of a strong association between inward irritability and overall severity and handicap of the neurosis confirms the expected. This

annoyance with their behaviour probably underlies the observation of Pollitt (1969) that patients suffering from obsessional neurosis are embarrassed about their seemingly incomprehensible behaviour, and so delay in seeking help.

‘Demand Characteristics’ in Body-Size Estimation in Anorexia Nervosa

LINDA PROCTOR and STEPHEN MORLEY

We asked 24 patients with anorexia nervosa and 30 normal controls to estimate their body-size several times, each time using different instructions. The degree of over-estimation was found to vary predictably with the wording of the instructions. Informing the subject that she had made an error without specifying the direction of the error resulted in reduced over-estimation on a subsequent trial, for both anorexics and controls. ‘Internally directed’ instructions were associated with a greater degree of over-estimation than ‘external’ instructions in both groups, but particularly in anorexic subjects. Our results indicate the necessity of controlling the ‘demand characteristics’ of such experiments.

The hypothesis that anorexics misperceive their body-size has received considerable experimental attention and the results have given it partial support (Garner & Garfinkel, 1981). One feature of the published data is a greater variation in the mean body-size estimates of the anorexics than in the estimates of controls. The source of this variation is unknown but there are reports that some anorexics under-estimate their body size although most over-estimate it (Touyz *et al*, 1984). Garner & Garfinkel (1981) have noted the relatively heterogeneous nature of many of the samples used in the experiments (e.g. variations in the history of the disorder; the presence/absence of vomiting; different attitudes towards eating and weight gain; presence/absence of depression and other indices of psychopathology; and variations in testing conditions). All these might contribute to the mis-estimation of body size.

One area which remains unexplored is the effect of the ‘demand characteristics’ inherent in experimental settings: it is possible that the variation in body-size estimations by anorexics is partly a consequence of idiosyncratic ways in which subjects interpret instructions and attempt to guess the experimenter’s hypothesis (Orne, 1969). Several reports exist of the effects of manipulating the instructions. Crisp & Kalucy (1974) and Pierloot & Houben (1978) instructed subjects to re-estimate their body-sizes after initial exposure to the task. Crisp & Kalucy (1974) observed a reduction in estimated body-size and claimed that the effect could only be obtained ‘within an overall psychotherapeutic relationship’ which would allow the patient to drop her defences. Although it is probable that this condition was not met in Pierloot & Houben’s

(1978) experiment, the second estimates they obtained tended likewise to be lower than the first, although the effect was not statistically significant. However, their second estimates were obtained under changed stimulus conditions: the previously darkened room was illuminated. The effects of instruction and setting were thus confounded. The same problem arises in the interpretation of Norris’s (1984) data. He requested subjects to re-estimate their body-size after they had had an opportunity to look in a mirror. They were explicitly instructed to use the ‘visual and tactile impressions gained at the mirror’ but were not told if their previous estimates were accurate or inaccurate. The anorexics significantly reduced their over-estimates of body-size on the second occasion. The problem is that it is not known whether they would have given more accurate estimates of body-size had they had access to the mirror before the first estimation. Norris also reports that the relationship between experimenter and subject in his study was not particularly close: it would therefore seem that a therapeutic relationship is not a necessary condition for the reduction of body-size estimates by anorexics. To return to the demand characteristics of the experimental setting; while it may be difficult to hide the general nature of the experimental hypothesis from intelligent and well-informed subjects (Szmukler, 1984), it is possible that the exact wording of the instructions to the subjects may have a predictable impact as their estimations of body-size. Some investigators have indicated that the exact form of the wording may vary from subject to subject (Button, 1979; Houben, 1979; both personal communications), which would probably magnify any variation due to the demand

characteristics inherent in the situation. It follows that increased precision in the instructions should result in reduced variability in the estimates.

The following paper reports on the effects of a systematic and controlled variation in the wording of instructions to subjects. We hypothesised that:

1. 'Ambiguous' instructions, which gave the subject no point of reference from which to make her judgement, would result in an over-estimation by anorexic subjects compared with controls. (As far as we can determine, our 'ambiguous' instructions were most like those used in other body-size estimation experiments).
2. Instructions which 'confronted' the subject with the fact that she had made an error in judging her body-size (without indicating the direction of the error) would lead her to reappraise her estimation, one way or the other.
3. 'Internal' instructions, which asked the subject to base her estimates on how she *felt* her body to be, would lead to over-estimation compared with 'external' instructions. ('External' instructions required the subject to estimate her body-size as if she were another person looking at her).
4. Both 'internal' and 'external' instructions would produce less variability in the subjects' estimations of body-size than 'ambiguous' instructions.

In addition to these comparisons we planned to investigate the uncontrolled factors—vomiting, in-patient/out-patient status, and time since last menstruation—which might contribute to variation in the sample.

Method

A total of 30 controls and 24 anorexic females were each given four different sets of instructions for estimating their body-sizes.

Subjects

The control subjects (all female) were nurses ($n=13$), secretaries ($n=11$), research assistants ($n=5$) or shop assistants ($n=1$). They were all healthy volunteers, recruited primarily from Addenbrooke's Hospital, Cambridge.

The anorexic subjects consisted of 12 in-patients and 12 out-patients: 9 were vomiters and 15 non-vomiters. All but two of the anorexics met criteria A, C, D, E and F for anorexia nervosa as described by Feighner *et al* (1972). The two exceptions had ages at onset of 26 and 34 years. Criterion B of Feighner *et al*—anorexia with accompany-

ing weight loss of at least 25% of original body weight—could not be used as information about original body weights was not available. Certainly all patients had lost a considerable amount of weight. Of the 24, five had had a menstrual period within the last month, seven more had had one within the last year; seven had last had a period 1–5 years ago; four had last menstruated more than five years ago; and one subject said that she had never menstruated. Two of the patients had children.

This sample of anorexics is more heterogeneous than those used in previous studies, primarily because out-patients were used as well as in-patients. However, if the effects of instructions are observable in such a varied sample, it would suggest that the differences found are quite robust.

Apparatus

We used a visual-size estimator built to resemble the machine used by Slade & Russell (1973). Body calipers were used to obtain actual body measurements.

Procedure

Subjects were tested individually in a totally dark photographic room at Addenbrooke's Hospital. The first author served as the experimenter for all subjects. Each session took about one hour.

The subject's height and weight (in normal indoor clothing) were measured. She was then told:

'I am going to ask you to make some estimations about various parts of your body. You will do this four times, with a short rest period between each session. The most important thing for you to do is to listen very carefully to my instructions at the beginning of each session, because they change each time. Are you ready to begin?'

The subject then took her place behind a line 155 cm away from the visual-size estimator, as in Slade & Russell's (1973) experiment, and the lights were extinguished. She was then given four sets of instructions (see Appendix), interspersed with short breaks. The order in which the instructions were given was determined in advance by means of a Latin Square, except that the 'confrontation' instructions were always administered immediately after the 'ambiguous' instructions. With each set of instructions the subject was asked to estimate the width of her face across the zygomas, bust (just below the armpits), waist (at narrowest point), and hips (at the widest point), as in Slade & Russell's (1973) study. She was also asked to estimate the depth of her stomach (the distance between the iliac crest and a point directly forward of this on the front side of her body) as in Button *et al*'s (1977) experiment. During the first trial only, the experimenter touched the subject's face, bust, waist, hips and stomach at appropriate levels to ensure that she understood what was to be estimated. Two estimates were required for each body part, one with the lights moving slowly outwards and one with them moving slowly inwards, as in Slade & Russell's study. The data were averaged for each trial (c.f. Button *et al*, 1977).

TABLE I
Means and standard deviations of age, height, weight and actual body widths of control and anorexic samples

	Controls (n=30) Mean (s.d.)	Anorexics (n=24) Mean (s.d.)	t
Age	21.8 (2.87)	24.5 (6.11)	—
Height (cm)	164.0 (5.70)	159.9 (4.37)	2.1*
Weight (kg)	58.9 (7.10)	46.7 (6.72)	3.296*
Face	11.4 (0.54)	11.2 (0.76)	—
Bust	26.1 (1.61)	24.3 (1.79)	3.79**
Waist	23.0 (1.57)	20.9 (1.99)	4.19**
Hips	32.0 (1.70)	28.3 (2.25)	6.88**
Stomach	19.2 (1.73)	17.4 (1.88)	3.75**

* $P < 0.05$ ** $P < 0.01$

Immediately after each set of estimates the subject was given some magazines to read outside the testing room for 3–5 minutes so that the experimenter could 'do some calculations', except that after the 'ambiguous' instructions the lights were switched on and the subject's actual body widths were ascertained using body calipers before she was excused from the testing room (the subject was not shown these or any other figures). She was then given the instructions for the 'confrontation' condition.

After completing the four sets of estimations, the subject was asked a series of questions about her vomiting, bingeing and general health. Finally, the rationale for the experiment was explained to the subject and her questions were answered.

Results

The basic descriptive statistics for the anorexic and control groups are shown in Table I. There was no significant difference between the groups with respect to age or the real width of the face. The anorexics in our study were slightly older than the average age of the samples reported by Garfinkel *et al* (1978), Pierloot & Houben (1978) and Slade & Russell (1973), but no older than the sample obtained by Button *et al* (1977). Our anorexics were slightly taller but slightly less heavy than the control group and were also, as expected, significantly thinner across the bust, waist, hips and stomach.

Body perception indices (BPIs) were calculated by averaging the values obtained on the two trials for each condition and expressing this value as a percentage of the real size (Slade & Russell, 1973). The average BPIs for each body part in each experimental condition, for anorexics and controls, are shown in Table II. These data were submitted to analyses of variance using the Multivariate programme of Finn (Finn, 1974). An initial ANOVA indi-

cated that there was no effect due to the order in which the instructions were given. The data were then collapsed over order. Under the 'ambiguous' conditions, the anorexics over-estimated all body parts compared with the controls, thus confirming the first hypothesis. 't' tests for each body site were all significant ($P < 0.001$, d.f. = 52 in all cases; face, $t = 3.63$; bust, $t = 4.47$; waist, $t = 5.47$; hips, $t = 6.06$; stomach, $t = 4.87$).

Confronting the subject with the information that she had made an error in her judgement produced the predicted change in the estimate of body-size, namely a significant reduction ($F = 63.59$; d.f. = 1,42; $P < 0.001$). However, there was no difference between anorexics and controls in this respect: inspection of the raw data showed that every subject reduced her estimate of body-size following the 'confrontation' instruction.

'Internal' and 'external' instructions resulted in different estimates of body-size, as predicted: 'internal' instructions produced larger estimates than 'external' ones ($F = 7.36$, d.f. = 1,42, $P < 0.01$). There was a significant difference between anorexics and controls in the way in which they responded to these instructions ($F = 6.85$, d.f. = 1,42, $P < 0.05$), with the larger effect being seen in the anorexic sample.

Post hoc analyses

Inspection of the means of variances of the anorexic group showed that despite the effects of the instruction on the means there was still considerable variation in the scores. *Post hoc* analyses were conducted to investigate the possibility that the sample might be stratified according to three criteria which might indicate the severity of the disorder: admitted vomiting as a way of controlling food intake; the in-patient/out-patient status of the patient; and the time since last menstruation.

TABLE II
Average Body Perception Indices (percentage of real size) for controls and anorexics under four different experimental conditions. Data in brackets are standard deviations

	Face	Bust	Waist	Hips	Stomach	Overall average
Controls						
Ambiguous	132.8 (24.0)	104.2 (14.8)	111.9 (15.9)	97.6 (10.4)	107.5 (17.6)	110.8 (12.06)
Confrontation	128.8 (20.5)	96.2 (13.3)	108.1 (11.6)	92.5 (10.9)	103.0 (12.7)	105.72 (14.23)
Internal	132.6 (20.9)	103.9 (11.7)	115.3 (11.8)	98.4 (8.3)	108.8 (17.4)	111.8 (14.73)
External	132.0 (20.4)	103.9 (13.6)	113.9 (14.8)	97.5 (10.8)	107.9 (16.8)	111.04 (15.61)
Overall	131.55 (21.5)	102.05 (13.40)	112.3 (13.65)	96.5 (10.16)	110.8 (16.25)	
Anorexics						
Ambiguous	188.2 (36.8)	121.2 (18.5)	146.4 (28.9)	122.5 (20.3)	151.1 (39.0)	142.08 (29.88)
Confrontation	148.7 (35.4)	109.2 (17.6)	131.3 (22.8)	109.8 (16.4)	136.3 (33.5)	127.06 (26.36)
Internal	161.1 (35.3)	120.9 (16.2)	145.3 (27.0)	121.1 (18.7)	147.3 (41.1)	139.14 (29.25)
External	153.6 (31.18)	118.0 (22.4)	140.1 (27.4)	117.4 (22.2)	142.5 (37.8)	134.32 (28.93)
Overall	157.9 (34.87)	117.33 (18.82)	140.77 (26.62)	117.95 (19.52)	144.3 (37.95)	

The small sample-size precluded any orthogonal comparisons of these indices and they were probably confounded. Three independent analyses of variance failed to reveal any systematic differences between groups. Moreover, grouping the data in this way had no effect on reducing the variances in the sample.

Discussion

The results of this experiment support the general hypothesis that anorexics over-estimate their body size. Direct support was also obtained for the hypothesis that the 'demand characteristics' of the experimental setting partly determine the degree of over-estimation. This second finding may account for some of the variation found between laboratories, and lends weight to Garner & Garfinkel's (1981) concern about the uncontrolled aspects of laboratory test settings. The impact of particular instructions is emphasised by the absence of any effect due

to the order of presentation of the instructions: this would seem to indicate that the estimates of body-size are influenced by the immediate stimulus conditions and not by the general laboratory setting. The fact that anorexics appear to be more affected than the control group by the change in the instructions emphasises that particular attention should be paid to the specification of test conditions.

The biggest effect of instructions was found in the contrast between the 'confrontation' and 'ambiguous' conditions. Indeed, confrontation produced a greater reduction in over-estimation than the 'external' instruction.

There are two notable points about our findings. Firstly, it would seem that no special relationship between the experimenter and the subject is necessary for reduction in over-estimation to occur: this study was conducted by an experimenter (L.P.) who had not previously met the subjects and had no therapeutic relationship with them. The second point is

that, without being told the direction of their error, all subjects (controls and anorexics) reduced their over-estimation in the 'confrontation' condition. This finding suggests that the experiment was at least partly free from the experimenter-bias artefact, as the experimenter had no expectations about the direction of the effect for the 'confrontation' condition. This finding is rather surprising and there is no obvious explanation for it. However, one possibility is that giving the subject any information at all about how to judge body-size ensures that she will pay more attention to the available cues. The fact that 'external' instructions produced more accurate estimates in the anorexic group can be construed as supporting this hypothesis. There is supporting evidence from other studies that providing cues for estimation will reduce previous estimates (Norris, 1984) or increase estimates in certain plausible conditions (Crisp & Kalucy, 1974). An explanation of this effect would be worth pursuing, as it may provide a more general explanation of why anorexics over-estimate their body size (Garner & Garfinkel, 1981).

Despite the apparent success of the experiment in differentiating between instructions, we found no effect of different instructions on the variation in the scores: this was contrary to expectations. Moreover, we were unable to account for the variation by examining subject characteristics which were not under experimental control. However, the range of subject characteristics we considered was rather limited and it is possible that allowing for other aspects would have provided a meaningful way of reducing the variance. Another possibility is that the anorexic group used in this experiment differs from those employed in other ones, being a little older than some.

The significant impact of the experimental conditions, and the fact that other studies have indicated that non-anorexics too over-estimate their body-size, suggest that it might be more profitable to investigate experimentally the general processes involved in body-size estimation rather than the supposedly pathological over-estimation by anorexics.

Acknowledgements

We thank Dr M. R. E. Proctor for building the body-size estimator and Dr P. J. Cooper for comments on a draft of this paper.

Appendix

Full text of the four sets of instructions given to subjects

Ambiguous

I am going to move these lights slowly outwards. Please tell me when the distance between them is equal to the width of your face/bust/waist/hips/distance from your back through to the front of your stomach (*each stated in turn*)

Now this time I will move the lights inwards and you tell me when to stop. Are you ready?

Confrontation

Rather than giving you a different set of instructions this time, I would like to repeat the ones we did just now, because in comparing your estimations with you actual sizes I find you really were wrong in your estimations. So listen carefully and let us see if you can be more accurate this time in your estimations. (*Instructions A were then repeated*).

External

Pretend for a moment that you are me, standing right in front of you, looking at you. Would you please estimate how wide I would see that you are across your face/bust/waist/hips/ from your back through to the front of our stomach? (*Each stated in turn*). The first time I will move these lights slowly outwards and you must tell me when to stop.

Now this time I will move the lights inwards and you tell me when to stop. Are you ready?

Internal

This time would you please show me how wide you feel yourself to be/you feel that you are across your face/bust/waist/hips/from your back through to the front of your stomach? (*Each stated in turn*). The first time I will move these lights slowly outwards and you must tell me when to stop.

Now this time I will move the lights inwards and you tell me when to stop. Are you ready?

Hormones, Mood and Sexuality

SIR: We write in reference to the recent article by Alder *et al* (*Journal*, January 1986, 148, 74-79). The research recorded is in line with the high standards that one has come to expect from the MRC Reproductive Biology Unit at Edinburgh. A number of interesting findings emerged:

Firstly, in terms of hormones, testosterone and androstendione median levels were lower in 5 breast-feeding women taking a progestogen-only pill, in comparison to 14 breast-feeding women who were not taking steroidal contraception.

Secondly, in the breast-feeding women testosterone and androstendione median levels were lower in those assessed at interview as having severely reduced sexual interest.

There is an apparent anomaly here, in that one might presuppose that those women taking steroidal contraception were certainly more concerned about the results of sexual activity (preventing a further pregnancy) and were possibly more interested in sexual activity. As mentioned, their testosterone and androstendione levels were lower, but no comment is made in the paper concerning their *actual* sexual interest, in comparison with the group not taking the pill and who had higher male hormone levels. This information would be of interest in assessing the association between male hormones and sexual activity in this group of people.

Drs Alder and Bancroft Reply

SIR: Drs Harris and Thomas raise an interesting point in their letter. If the reduced sexual interest in our sub-group of breast-feeding non-pill using women was a result of their lower androgens, did the pill using group whose androgens were also low report sexual interest, and if not why not?

The progestogen-only pill using breast-feeders did not differ from the non-pill using breast-feeders in either sexual interest or activity. This highlights the complexity and often contradictory nature of the evidence of androgens in the sexuality of women which we pointed out in the paper. It is of course

possible that the low level of androgens in the non-pill sub-group was a result, not a cause, of the low sexual interest. Or, alternatively, as we warned in the paper, they may have had lower androgens to begin with (i.e. before pregnancy). Although we have no evidence that our pill users were either more concerned about the result of sexual activity or more sexually interested before starting on the pill, they may have differed in some relevant way, e.g. their level of sexual interest may have been brought down by the pill or lowered androgens to the same level as the non-pill users. It is also possible that the androgen lowering effect of the contraceptive pill is different to that of breast feeding in some obscure way.

As yet there is little other evidence of the effects of progestogen-only pills on androgen levels. In a previous study of combined oral contraceptive users (Bancroft *et al*, 1980) we compared women with and without loss of sexual interest. Both groups had equally low androgens. In the "normal interest" group testosterone levels were positively correlated with self-ratings of sexual interest; this was not so in the low interest group. The role of androgens in female sexuality remains an enigma.

Homosexuality in Monozygotic Twins Reared Apart

SIR: I was very surprised to read that female sexuality may be an acquired trait and male due to complex interaction, in which genes play some part (*Journal*, April 1986, 148, 421-425). It is quite clear that the authors are aware that their sample is small, but the consequences are not accepted (i.e. they dare make conclusions as outlined above). Homosexuality is not a rarity (despite the fact that collecting a large enough sample of homosexual

monozygotic twins reared apart is) and care should be exercised when trying to generalise about it.

Dexamethasone Suppression Test

SIR: I refer to the review article by Braddock on the dexamethasone suppression test (DST) (*Journal*, April 1986, 148, 363–374), with particular respect to nonspecific factors which might affect non-suppression. I feel the omission of the effects of caffeine merits updating.

Uhde *et al* (1985) studied 22 normal volunteers and depressed patients (diagnostic criteria not specified). The DST consisted of dexamethasone 1 mg at 11 pm and a 4 pm cortisol sample. Analysis was by radioimmunoassay. All subjects were given a single blind placebo controlled challenge of 480 mg caffeine (equivalent to about 4 cups of filtered coffee) between 2 and 2.30 pm. Caffeine was found to increase the mean post-dexamethasone cortisol value from 2.3 to 5.3 $\mu\text{g/dl}$ ($P < 0.001$). For both volunteers and patients, when using the 5.0 $\mu\text{g/dl}$ standard cut-off point, non-suppression occurred in 14% on placebo and 36% on caffeine. This dose of caffeine is not unusual when compared to the average daily consumption (Gilbert *et al*, 1976), and indeed in psychiatric patient populations more caffeine may be used (Galliano, 1982). In addition, depressed patients in particular may actually increase consumption of caffeine as a result of their illness (Greden *et al*, 1978; Neil *et al*, 1978). Caffeine therefore should be added as an additional non-specific factor which might affect non-suppression.

Is Hysteria (Conversion Reaction) Still Alive?

SIR: The article by Shalev and Munitz entitled Conversion Without Hysteria: A Case Report and Review of Literature brings out the controversy which exists around the diagnosis of hysteria (*Journal*, February 1986, 481, 198–203).

My experience in a psychiatric hospital in India in a semi-urban area is that there is a well defined group of patients who can be given a diagnosis of hysteria. We have described the clinical features of such a group of 276 patients (Subramaniam *et al*, 1980). Similar patients are very common in most of the psychiatry clinics in India. The following are the common clinical features: presence of physical symptoms, more often monosymptomatic, in motor or sensory system without any organic basis; pre-morbid hysterical personality traits; age of onset of symptoms before 20 years; more among females; dramatisation of symptoms with belle indifference; presence of some unconscious conflict not necessarily sexual in nature and complete recovery with psychoanalytically oriented psychotherapy. Any physical symptom in the absence of an organic basis should not be considered hysterical. If this is established, it is likely that hysteria or conversion reaction will continue in spite of the obituaries pronounced on it by Slater and others.

On Serious Violence During Sleep-walking

SIR: Drs Oswald and Evans (*Journal*, December 1985, 147, 688–691) presented some interesting material on somnambulism, including a case of a criminal act committed in sleep. We report another case.

Case report: A young man stayed overnight at his mother's. In the middle of the night he was awakened by an unpleasant dream in which his mother criticised and attacked his girlfriend. He sat up and dressed, with the dream going on in his head, but aware of where he was. Suddenly he got the thought—as if a voice in his head told him—that he should threaten his mother not to be so derogatory and aggressive to his girl-friend. So he went to get a hammer in the basement and went to his mother's bed. Just as he was about to wake her she moved in her sleep. To his surprise he hit her again and again with the hammer without a conscious thought, until after a while he

realized what he was doing. Seeing the blood he left and went around the streets. A little later he returned to his mother's house, hoping to see an ambulance in the street. Next he went to her door, hoping to hear some sign of life from inside. Neither of his hopes were fulfilled, so he went to his own home, where hours later, he was arrested for the murder of his mother.

Throughout his earlier life the young man had suffered from frequent nightmares and as a smaller child he had been known to sleep-walk. The relationship between mother and son had never been very good and it had worsened because of the mother's disapproval of the son's girl-friend. In the days before his mother's murder the young man's dreams about his mother had been extremely vivid. Whenever he woke up he had to concentrate for a time in order to tell dream from reality. The young man stressed convincingly—and he was supported by the evidence of others—that it was very far from his nature to react with violence.

In the requested psychiatric report it was concluded that the young man was in good health physically, examination by specialists in neurology and EEG revealed no abnormalities. Psychiatric examination showed that he was immature and insecure, but there were no decisive signs of psychopathology. A similar conclusion was drawn from a full scale psychological test, where, in addition, evidence of difficulties in controlling aggressive impulses were seen.

It was claimed that at the time of the crime he had been in a somnambulistic state, a state of reduced consciousness and consequently he had been in psychosis-like condition. According to the Danish Penal Code, section 16—"Acts committed by persons being irresponsible owing to psychosis or similar conditions or pronounced mental deficiency are not punishable"—it was suggested that the crime should be dealt with by treatment and supervision. The case was presented to the Danish Medico-Legal Council, and the Council too concluded in favour of a psychosis or a similar condition. The court followed the medical experts. Discharge took place soon after, and in the first year the young man regularly consulted his psychiatrist, who described him as still immature and periodically anxiety-ridden. In the periods of anxiety he was not able to sleep without sedative medication. He was again admitted to hospital for a time, mostly because of lodging-problems. In the following years he saw his probation officer regularly, and seemed to undergo a positive development, both emotionally and socially. Seven years after the criminal act he was tested by the same psychologist who examined him during the period of mental observation. The psychologist reported the young man to be quite well functioning and compared with his earlier condition he was now quite well controlled, almost inhibited emotionally. Thus the test indicated character neurosis and thereby confirmed the clinical impression of personal stabilization.

Our case might be found somewhat more controversial than those presented by Oswald and Evans—some motive could be postulated and the degree of consciousness-reduction is not quite clear. Still, as

the border between sleeping and waking is perhaps not very well defined, we have great sympathy for our older colleagues who remembered the possibility of somnambulism.

In his precise and thorough survey of the subject Schmidt (1943) differentiates somnambulism from epilepsy, discusses psychiatric and forensic aspects and presents material on 15 cases of homicide. Furthermore a nosological subdivision is made; along with the sub-type called the dreamy type ("Die traumhafte Form"), there is a discussion of crimes committed—as in our case—while under the influence of a dream. In his conclusion Schmidt advocates that somnambulism should legally be treated like psychosis. The question whether the defendant is responsible or not must be answered with a no ("verneint"). In these cases the medical opinion is therefore fundamental. We close this letter, like Schmidt did his paper, by observing that even the most careful examination can leave the investigator in doubt.

SIR: The article by Oswald and Evans (*Journal*, December, 1985, 147, 688–691) states that sleep walking can be accompanied by violent injury to the self or others. We would like to report another case.

Case report: A 25 year old divorced man was admitted to our service, having been charged with the attempted murder of his *de facto* wife. The circumstances surrounding the attack were unusual. After an uneventful day he helped his wife to prepare the evening meal, played a game of dice and then watched a movie on TV. On finding this uninteresting they had another game of dice and retired to bed at midnight. His wife's young son was ill and at that time was sleeping, in a single bed, in their room. The boy woke up several times during the night, vomiting, and our patient and his wife at various times got up to attend to him. This occurred till at least 2.00 am. His next recollection was of waking up as it was becoming light and seeing his wife sitting at the corner of their bed with something around her neck. He said that it looked like a piece of string or rope. He pulled it from her neck as a result of which she fell on the floor. He immediately ran down the hallway to the kitchen and telephoned for an ambulance

and the police. His wife was taken to hospital where, fortunately, she made a good recovery. He was charged with attempted murder and taken into custody. He denied any conflict with his wife; she was pregnant and they were both looking forward to the birth of their first child. He specifically denied any disagreement with her before they went to bed, while no sexual activity or attempted sexual activity occurred between them that evening. His wife, who left him after the assault and moved interstate, confirmed his story.

He came from a somewhat troubled background, in that his parents separated when he was a child, and for a time he was placed in a Boy's Home before reuniting with his father. He had a very close relationship with his father, both shared a common interest in black magic and seances. He was very distressed by the death of his father some years earlier and continued to maintain the contact with him by wearing some of his clothes on a regular basis. It was subsequently discovered that the article used in the apparent attempt to strangle his wife was the cord of the dressing gown previously owned by his father. Additionally the attempted strangling occurred very close to the anniversary of his father's death. Although the patient had a history of impulsive suicidal attempts, coupled with alcohol and drug abuse, these behaviours had not been evident for some time and there was no evidence to suggest that he had been so troubled, in any way, at the time of the attack on his wife. Again this history was confirmed by her. Our patient claimed that for some days prior to the attack his sleep pattern had been disturbed with night terrors/nightmares.

Physical examination and a range of laboratory investigations were normal. A skull x-ray, an EEG and CT scan of his brain were also normal. Neurological opinion was sought but no pathology was identified. Neuropsychological testing did not reveal any abnormality. An MMPI demonstrated a hypochondriacal profile.

At his trial, the defence raised the possibility of somnambulism which, at law, would fall within the category of non-insane automatism. He was found guilty by the jury and sentenced to 15 months hard labour, with a non-parole period of 11 months. This was suspended in favour of a probation order of three years with a condition to undertake any medical treatment as the supervising probation officer might direct.

Although it is clear that this man had an abnormal personality structure and some unusual interests, no convincing explanation or precipitant has ever been identified with respect to his assaultive behaviour. He had a history of disturbing dreams dating back to childhood. He had a vague partial recollection of one sleep-walking incident, some years earlier, when having gone to bed he woke up in the kitchen. No violence was exhibited on that occasion.

Tardive Dyskinesia and Parkinsonism

SIR: Tardive dyskinesia (TD) and drug induced Parkinsonism (PS) both occur in association with the use of neuroleptics. The co-existence of TD and PS has been documented (McCreadie *et al*, 1982) but interest has mainly centred on the unmasking or the amelioration of dyskinesia either by anti-cholinergic agents (Chouinard *et al*, 1979) or of GABA agonists (Gerlach, 1977). The subject has also been studied using multivariate statistics on populations who exhibit neuroleptic induced extra-pyramidal effects (Kidger *et al*, 1980). These studies report that three independent factors emerge which approximate to the clinical syndrome of Parkinsonism, oral dyskinesia and akathisia. No study appears to have specifically considered the relative severities of the TD and PS syndromes when they co-exist and no comparison has been made with a control non-dyskinetic Parkinsonian cohort.

The aim of our study was to test the null hypotheses that the severity of PS in a TD group is no different from that of a control group exposed to neuroleptics but without TD. We also examined the correlation between the severity of TD and PS in our index group. The groups were carefully matched for age, sex, and type of medication. The 16 patients in each group were rated on the Abnormal Involuntary Movements Scale (AIMS) (Guy, 1976) and the Webster rating scale (Webster, 1968). The criterion for diagnosis of TD was a clinically recognisable disorder and a score of two or more on any item on the AIMS. The patients were on long-stay wards and had a primary diagnosis of functional psychosis. All subjects were on neuroleptics at the time of assessment and 9/16 in each group had been on long-term anti-cholinergics.

The mean age of the index group was 64.75 years (range 50–82) and of the control group 63.82 years (range 50–87). The Webster scores were compared between the groups and were not statistically different ($t = 0.926$, d.f. 30, NS). There was no correlation between the total AIMS and Webster scores ($r = -0.08$). We conclude that TD patients over 50 years have PS to a similar degree as an age- and sex-matched group without TD. In addition, in the TD group, the severity of PS did not predict the severity of TD. The co-existence of TD and PS and our findings of an independence of their relative severities calls into question the currently held view that PS results from a blockade and TD a hypersensitivity of dopamine receptors (Marsden *et al*, 1980). In our view the two conditions are either mediated through different dopamine systems or through independent but related neurotransmitter systems which have not yet been fully elucidated.

We thank Drs T. A. Kerr and I. N. Ferrier for their assistance.

Mania Following Bereavement

SIR: I read with interest Rosenman and Taylor's case report of mania following bereavement (*Journal*, April 1986, **148**, 468-70). The authors state that such reports showing this association are uncommon. I report two further cases.

Case reports: (1) A lady who had no previous psychiatric history, first presented aged 49 years, two months after the sudden death of her husband. He had taken his own life whilst she was at work. At first, she grieved appropriately but six weeks after her bereavement she became restless, irritable and garrulous. She returned to normal mood within one month following treatment with neuroleptic medication and ECT. Four years later her mother died of carcinoma. She grieved initially but soon became cheerful. By the time of presentation, one month after her bereavement, she was restless, overtalkative, sexually disinhibited, giggly and expressed paranoid ideas with regard to her neighbours and sons. She said that nursing her mother for eight years had imposed a great strain on her and that her behaviour was a reaction to the lifting of this strain. She became euthymic within two months on treatment with haloperidol but 18 months later presented with a further manic episode. This occurred three weeks after a celebration in her husband's family to which she had not been invited and she had been initially very upset. She has been well in the nine years since the last affective episode.

(2) A 58 year old lady with a previous history of bipolar affective disorder presented the day after the funeral of her husband who had died suddenly of a myocardial infarct one week previously. Within 24 hours of his death she became restless, overtalkative and insomniac. On admission she talked incessantly and maintained that she felt "hilarious" in spite of occasional tearfulness. She believed she had special powers of healing people and that the television was telling her what to do. She could hear her husband talking to her. Her mood gradually stabilised on treatment with haloperidol, but one month after the bereavement she became depressed. She was then successfully treated with an antidepressant and discharged. One year later she presented with depression requiring treatment with ECT. Her mood stabilised but after a visit to her husband's grave three months later, she became manic with mixed affect. This resolved and she has been well for the last six months.

Rosenman and Taylor discuss the mechanism of manic response to bereavement. They cite the Post *et al* (1981) finding that a previous history of affective disorder predisposes to a rapid onset of mania. These two cases support this: (1) with no previous history of affective disorder did not develop mania until six weeks after her husband's death and (2) with a well established bipolar affective disorder developed mania within 24 hours of her bereavement. That repeated episodes of illness establish a facilitated pathway by which rapid changes of mood could occur, may be further supported by the recurrence of mania following case 2's visit to her husband's grave 15 months after his death, and following case 1's perceived rejection by her in-laws.

SIR: The case report by Rosenman and Taylor (*Journal*, April 1986, **148**, 468-470) of mania following bereavement was of considerable interest. I report another two cases.

Case reports: (1) A 46 year old divorced engineer was admitted as an emergency in a hypomanic state on the evening of his mother's funeral. Instead of returning home from the funeral he had gone to his place of work where his behaviour had caused concern, the work's medical officer had arranged admission. On admission he was dressed in a

morning suit and was constantly pacing the floor, his mood elevated, he was overbearing and slightly aggressive in manner. There was marked pressure of speech and flight of ideas. This state persisted for six weeks and was followed by a period of depression. There is no evidence that he was hypomanic prior to his mother's death. There had been a hypomanic episode some two months beforehand but this lasted less than a month and there is well documented evidence that his mood remained stable up to the time he had leave from work after his mother's death.

Almost two years later his father died and five days afterwards he was again admitted in a similar state. Again there was no evidence to suggest that his mood was elevated before the event.

This patient had an established manic-depressive disorder and had been subject to mood swings with no apparent precipitant. On these two occasions and on a possible third occasion when a hypomanic episode followed his wife leaving him, there was a clear precipitating event.

(2) A 24 year old single woman was admitted from the police station in a manic state. She had been found wandering naked and was grossly overactive, her mood alternated between elation and aggression, her speech was constant, with flight of ideas, punning and clang associations. Three weeks previously her adoptive father had committed suicide. She had felt pressure from the family as there had been a suggestion that she had been responsible for her father's depressive illness. During the three weeks after his death she had become progressively more disinhibited, over-active and promiscuous. Again, there is no suggestion that her mood was different before the death.

She had no previous history of affective disorder. However, a year before this episode she had been diagnosed as having a personality disorder. It is possible that her behaviour at this time indicated a mild hypomanic episode. Since the reported incident she has had one depressive swing starting three days after she gave birth. This depressive swing was followed by a period of mild hypomania.

I am grateful to Dr F G Spear, Consultant Psychiatrist, for permission to report these cases.

Lithium Carbonate and Piroxicam

SIR: The report by Walbridge and Bazire (*Journal*, August 1985, 147, 206-207) of an interaction between lithium carbonate and piroxicam prompts us to report details of a patient who also experienced lithium toxicity, probably attributable to this combination.

Case report: A 62 year old female with a 20 year history of manic depressive illness was started on lithium in March 1984 during her twelfth admission to hospital. Initially her renal function was checked and showed a plasma creatinine of 80 $\mu\text{mol/L}$. Her plasma lithium was stabilised at

0.6-0.75 mmol/L (checked monthly) with a dose of 800 mg of lithium carbonate at night. Ten months later, on 24.1.85, piroxicam 20 mg daily was prescribed for osteoarthritis of her right knee. Concurrent medication was as follows: amitriptyline 150 mg at night from 16.1.85 (previously on dothiepin 75 mg at night started before 1984), chlorpromazine 175 mg daily (from before 1984), procyclidine 5 mg tds from 14.1.85, and temazepam 20 mg at night from 11.1.85. Her January lithium level (taken on 8.1.85) was slightly raised at 0.85 mmol/L, possibly due to a recent loss of weight. At the end of January, she became noticeably agitated and tremulous: and during the next few days developed ataxia. During this period she was eating and drinking very little. A lithium level, done on 7.2.85 was 2.85 mmol/L with a raised plasma urea of 12 mmol/L and plasma creatinine of 142 $\mu\text{mol/L}$. All drugs were stopped and i/v fluid replacement started. Plasma lithium fell in four days to 0.35 mmol/L and plasma creatinine was inside the normal range (60-120 $\mu\text{mol/L}$) within 48 hours. Renal function tests continue to show mid-range values at the present time. She was also treated for an *E. coli* urinary tract infection with Amoxycillin starting 8.2.85. The lithium toxicity in this patient was probably exacerbated by dehydration and a urinary tract infection, but we consider that a piroxicam/lithium interaction could have contributed significantly.

Although the lithium/non-steroidal anti-inflammatory drug (NSAID) interaction has been well established, the mechanism is not completely understood. One mechanism, that of suppression of renal prostaglandin synthesis by NSAIDs leading to a fall in GFR and thus a reduced clearance of lithium has been clearly implicated in some cases (Nadarajah & Stein, 1985). This is reversible but the risk may be greater with NSAIDs with a long half-life (Adams *et al.*, 1986). Walbridge and Bazire suggest using an NSAID with a short half-life, e.g., ibuprofen, to reduce the extent of the interaction; however reports have shown marked increases in plasma lithium concentration within a short time of initiation of ibuprofen therapy (Ayd, 1985; Leftwich *et al.*, 1978).

In the light of this, it has been of concern to us that ibuprofen is now a non-prescription drug in the UK and can be bought freely over the counter. With this in mind, we now counsel our lithium patients on various aspects of their therapy with the use of information cards which specifically refer to the possibility of an interaction with ibuprofen. We ask our patients to show their card to any chemist they buy medicines from.

Seasons of Birth and Sub-Types of Schizophrenia

SIR: Many studies show disproportionately higher rates of schizophrenic patients born during the winter months (Hare *et al*, 1974; Torrey *et al*, 1977). We undertook a study to find out if there is an excess of winter births among schizophrenic patients, and in particular if seasonal variations are related to the gender and sub-types of schizophrenic patients. We examined the seasons of birth of 472 patients with the diagnosis of schizophrenia admitted consecutively to a teaching hospital over a period of 5 years. We also studied the gender and paranoid vs non-paranoid sub-types of this subject group.

The total group did not show an excess of winter births, neither did the total male ($n=193$) and total female ($n=279$) schizophrenic patients. However, the male paranoid schizophrenic group ($n=102$) showed a significant ($P=0.05$) increase of births during the first quarter of the year. The different sub-group of female patients showed a homogeneous distribution of seasons of birth. We found a fairly stable distribution of seasons of birth among both the male and the female non-paranoid sub-groups (those with a greater genetic loading). According to Huxley's "genetic morphism" hypothesis (Huxley *et al*, 1964), the genes endow these sub-groups of patients with better capabilities of resisting various environmental factors. The homogeneous distribution of birth among the female paranoid sub-group could be explained on the basis of certain "built-in" protective factors for the female population (Seeman, 1981). Nature has provided the female with protective factors which may be responsible for their later onset of illness, better response to neuroleptics, fewer relapses, better work record, greater social adjustment, and significantly fewer peri-natal problems as compared to their male counterparts. Although there have been several explanations, the significantly greater number of

births of males in the paranoid sub-group during the winter months has been explained on the basis of the two hypotheses, viz. pre- or perinatal birth trauma or the viral infection hypothesis (Torrey & Peterson, 1976). They contend that because of the higher prevalence of viral infection during colder months, the schizophrenic patient is infected with slow or latent viruses, which alter the function of nerve cells in critical areas of the brain without altering the histological structure. Since the direct evidence of viral infection is lacking, we proceeded to test the first hypothesis, i.e., that subtle birth trauma later predisposes to the development of schizophrenia in susceptible individuals. For this purpose we examined the birth dates of 44 (38 males and 6 females) patients with the diagnosis of minimal brain dysfunction admitted consecutively during the same period as those of our schizophrenic sample. This group of patients is known to have high incidence of subtle brain insults. However, we failed to find any seasonality of birth in this sample. Therefore, we may infer that in our sample the significant increase of births among male paranoid schizophrenics during the winter months could not be explained by factors related to peri-natal trauma. This finding tends indirectly to give more weight to the viral hypothesis of schizophrenia, especially among male paranoid schizophrenics.

Book Reviews

Dangerousness: Probability and Prediction, Psychiatry and Public Policy. Edited by Christopher D. Webster, Mark H. Ben-Aron and Stephen J. Hacker. Cambridge: Cambridge University Press. 1985. Pp. 236. £25.00.

It is sad to reflect that of all living creatures, man has the greatest propensity to be in conflict with himself and with others. Aggression, and its counterpart violence, both of which carry distinct overtones of dangerousness, would appear to be innate. If this is so—and the evidence is pretty irrefutable—then, given unusual or exceptional circumstances, we can all behave dangerously. For example, the *crime passionnel*, so often carried out with unbelievable violence and ferocity, is equally often at odds with the day-to-day behaviour of the assailant. And what happens to Joe Bloggs when he is transformed into Private Bloggs is the stuff that history books are made of.

What, I suppose, this book attempts to do is to narrow the field to the probability and prediction of dangerousness in those suffering from mental disorder, although, to my mind, this is a factor which must add yet another dimension of uncertainty to the dilemma.

Professor John Gunn of the Institute of Psychiatry, London, who is, incidentally, the only non north-American contributor, sets the scene unambiguously in his Foreword. He writes "... we learn, yet again, that our ability to forecast which people will do harm in the future is very poor". The implicit pessimism is almost painfully amplified in an excellent, yet hardhitting, chapter by Professor Alan A. Stone. He alleges—and few of us who turn an honest penny in the practice of Forensic Psychiatry in Courts of Law in the UK would dare disagree—that "the question of dangerousness, the statistical prediction of violent behaviour... has become the chief battlefield in the struggle between law and psychiatry". He goes on to deliver a flurry of telling blows to the psychiatric chin. "I found the published studies of prediction woefully inadequate, poorly conceived, wrongly interpreted and well below any acceptable standard of scientific research or even solid clinical experience", he opines.

The same sort of scepticism, although far more delicately expressed, is to be found in the contribution of Professor Cyril Greenland. He quotes Dr Barry Boyd as saying that only 10% of the patients detained under his care in a Canadian maximum

security hospital would kill again on discharge, and that he would be delighted to set the remaining 90% free if someone could tell him reliably who they were. It could be added that our own Dr Patrick McGrath, lately of Broadmoor Hospital, has oftentimes been heard to express the same opinion, it could be added.

For my money, far and away the most intriguing chapter is that by Professors Christopher Webster and Mark Ben-Aron entitled, "Dangerous Doctor Fischer: a case history in clinical assessment." Dr Fischer is the central figure in Graham Greene's allegorical, spine chilling novel, *Doctor Fischer of Geneva or The Bomb Party*. Greene with his incomparable insight into the vagaries of the human psyche brilliantly portrays one of that most evil and dangerous breed of psychopaths (Shakespeare does a similar job with Iago), the jesting destroyer. It matters little that in the end, after repeatedly corrupting and humiliating a coterie of greedy toadies, Fischer falls victim to his own corruption and kills himself.

All in all, for those of us who like myself had hoped to find in this book some sort of philosopher's stone that would transmute the base metal of educated guess-work into the gold of certainty, will be disappointed. Perhaps, for the time being at any rate, we will have to fall back on that well-worn saw—nothing predicts behaviour like behaviour.

HENRY R. ROLLIN, *Emeritus Consultant, Horton Hospital, Epsom*

Using Metaphors in Psychotherapy. By Philip A. Barker. New York: Brunner-Mazel, 1985. Pp. 221. \$25.00.

The title of this book excites the hope of a general examination of the therapeutic use of metaphors in psychotherapy. It soon becomes apparent however that the major emphasis is on strategic and systemic approaches in child, adolescent and family psychotherapy. A paragraph is given to the use of metaphor in psychoanalysis and behaviour therapy and the other therapies are left to fend for themselves. The same may be said of the examination of metaphor. The definition of the word is extended, not without justification, to focus on the use of stories, anecdotes, metaphorical objects and activities as indirect instruments of psychotherapeutic change. The relationship of metaphors to symbols and

symbolic function in dynamic psychology referred to by well-known psychoanalysts is not discussed.

Once the reader realises that what appears to be a whole story is only a part of it and that this is a primer or guidebook on the therapeutic use of stories, anecdotes, and analogies, it can become a helpful and thought-provoking book.

The first three chapters discuss the past and present use of extended metaphors as an indirect, entertaining, informative and flexible way of communicating, and of their place particularly in the more directive strategic and systemic therapies. The author reflects on their power to reach hidden emotions, to reduce resistance, to reframe, redefine and suggest solutions to problems, to restore confidence and competence and what is rather chillingly called "embed" directives. Then there is a classification and discussion of various types of therapeutic metaphor. These chapters are useful in setting out some of the principles underlying the therapeutic use of metaphors and will be of particular interest to family and eclectic psychotherapists and students of Milton Erickson's approach to whom the author expresses his indebtedness.

Succeeding chapters focus on the use of metaphors in the establishment of different kinds of treatment goals; the treatment of developmental problems; conduct disorders and other behavioural problems; anxiety and depression; family problems and difficulties in wider social contexts—and a variety of miscellaneous issues, and finally with the practical delivery of metaphors, and the important issue of gaining rapport.

The book is structured so that each chapter starts with a story, ends with a summary and with a practical exercise in constructing "metaphorical approaches" to particular problems. I think some readers may find one or two of the stories too long, some aspects rather repetitive and the practical exercises particularly daunting if worked on alone, rather than in a group or seminar. In fact, the author's statement in the introduction, that "the use of metaphors is surprisingly easy once rapport is established" sets a tone of untroubled optimism which lingers on despite a warning illustration of a possibly resistant family, statements on the importance of fitting the metaphor to the client and observing verbal and non-verbal responses.

Nevertheless, so long as these limitations are kept in mind, the book contains a great deal of valuable information, and deserves a place as an introductory text to this intriguing area of communication.

BRIAN LAKE, *Consultant Psychotherapist,
St James's University Hospital, Leeds*

General Hospital Psychiatry. By Michael Alan Taylor, Frederick S. Sierles and Richard Abrams, London: Collier Macmillan. 1985. Pp. 463. £35.00.

Let us immediately clarify a misunderstanding about the title of the book which may well arise among psychiatrists working in general hospitals. The term general hospital psychiatry is beginning to be used in favour of the more cumbersome consultation/liaison psychiatry to connote the professional activities of psychiatrists who work within district general hospitals as opposed to mental hospitals.

This, however, is a textbook of in-patient general psychiatry. The idea is that no previous text is geared towards the modern style of psychiatric practice; biologically and pharmacologically based usually occurring over fairly short periods of in-patient stay in wards "designed to look like living rooms". Thus the authors write as much like physicians as they can—under the circumstances. The importance of making a correct diagnosis is emphasised and a few "diagnostically powerful" symptom patterns described, although I found these often contentious and unconvincing. Happily, the authors place great importance on observation of the patient for a few days before starting treatment, a rule which they admit is nearly always broken.

The mental state examination is given the grand but misleading title of Neuropsychiatric Examination. A separate Behavioural Neurologic Examination is then described which is, in essence, the detailed cognitive mental state examination. A second section then deals with patient management including chapters on various forms of treatment except psychotherapy. There is one chapter on Consultation/Liaison Psychiatry. The final section has 16 chapters on the major diagnostic groupings in psychiatry.

This is an interesting and well-written book. It covers psychiatry from a specific viewpoint, making no attempt to include all available treatment options and sticking rigidly to a determinist, behavioural and neurologic framework. As a result, the great value of this approach in some areas is apparent and therefore it is a book which, particularly in the USA, should be of considerable interest. It is highly critical of pseudo-mechanistic interpretations of disease as found for example in some Freudian terminology.

However, in other areas, the failure to consider any form of psychotherapy causes some passages to appear lightweight and superficial. Neuropsychiatry is still in its infancy and to attempt to expand it to cover all conditions presenting to the psychiatrist

threatens to break the bounds of credulity. To say that eventually we will know enough about the brain to carry out that exercise successfully presupposes that the materialist-determinist view of the human being proposed by Ryle is correct. We may however quite legitimately conclude that Karl Popper was right to derisively call this a "promissory materialism", and that therefore it is likely that psychotherapeutic skills will be in demand for some considerable time.

CHRISTOPHER THOMPSON, *Senior Lecturer in Psychiatry, Charing Cross and Westminster Medical School, London*

Ethical Issues in Psychosurgery. By John Kleinig
London: George Allen & Unwin. 1985. Pp 152.
£15.00 (hb) £5.95 (pb).

This is an interesting book, written by an academic philosopher, which is easy to read. It could almost as well have the title, "Ethical Issues in Psychiatry", because it is noted early on that a number of psychiatric treatments, including "...drug therapy, aversive conditioning and even token economies must confront the problem of diagnosis, irreversibility and consent that psychosurgery so sharply raises". Thus, the general psychiatrist will find relevant reviews in, for example, the sections dealing with the classification of psychiatric conditions (illness or deviant behaviour; treatment or punishment), placebo responses, and alleged social influences on psychiatric attitudes.

Those who have managed to get through the many pages of the "Consent to Treatment" draft document prepared by the Mental Health Act (MHA) Commission, may turn to the chapter on consent in this book with some eagerness. The subject is dealt with sensibly although much will be well known to psychiatrists (such as, why get consent?) and it does not become so confusingly entangled with law as does the Commission's document.

Understandably the need for more information and more scientific method in assessing psychosurgery is frequently stressed in the book, although the author himself indulges in some speculation. He considers that the wide-spread use of standard pre-frontal leucotomy in the 1940s was because the "The Second World War produced a large number of psychological casualties (which) constituted a serious logistical problem" (p. 7). He asserts that this situation created pressures for the too frequent use of psychosurgery, but no evidence is offered in support of this view, which is unique to this book as

far as I am aware. Similarly, the author feels able to state, with regard to the development of psychosurgery, that concern for patients "was clouded by... the desire to enhance the scientific or other ambitions of its practitioners" (p. 12). This acid comment could also do with some supporting facts.

The author certainly foretells of the coming of our MHA Commission. His answer is "no" to his own question, "is the patient's consent sufficient to justify psychosurgery?". The patient's consent cannot be relied upon because "some... would probably be willing to consent to an inappropriate treatment" (p. 60), which assumes that the neurosurgeon and psychiatrists advising the patient cannot give reliable opinions about appropriateness (perhaps because of "ambitions", see above). It follows, one supposes, that unambitious MHA Commissioners are needed.

An indictment is clear but not explained: the author observes that some "may resent... monitoring and regulation, especially if enshrined in law, but it is only because their profession has shown itself incapable of, or unwilling to, regulate itself that such measures are proposed" (p. 21). In what way did we not regulate ourselves?

P. K. BRIDGES, *Physician in Psychological Medicine & Senior Lecturer, Guy's Hospital, London*

Psychosomatic Medicine and Liaison Psychiatry: Selected papers. By Z. J. Lipowski. New York: Plenum. 1985. Pp. 453. \$39.50.

It is a bold step to publish one's collected papers, since it assumes an audience for work written long ago. Usually, such books lie unread in libraries, but this book deserves a better fate since Professor Lipowski has played a rather remarkable role in the development of what has become known as "liaison psychiatry". During the last 20 years, this has been established as a North American sub-specialty, becoming a part of almost every training programme and accepted in every substantial general hospital. Although, for most of this time, the predominant mood has been one of optimism, recently reductions in funding and the swings of fashion have led to doubts, falling morale and pessimism about the future. It is a good moment to take stock.

What has Professor Lipowski's contribution been to liaison psychiatry? He has undoubtedly been a man of his time who had the good fortune to begin his career as traditional psychosomatic medicine was expiring and as psychiatry was turning back to clinical medicine. However, there can be little doubt that his vigorous promotion of the clinical and academic aspects of his subject have helped to establish

its public image. By wide reading and by judicious use of what must be a remarkable card index, he has been able both to reflect what has been going on around him and to be in the forefront of crystallising new ideas. Starting with a major three-part review of psychosomatic medicine in 1977, he has closely chronicled the development of clinical practice and thought. Although he has described his own clinical services his main creative contributions have not been of clinical innovation or research. They have been theoretical and descriptive, the formulation of the principles of liaison practice, description of the main factors affecting individual response to physical illness and, most recently, a clarification of the syndromes forming organic mental disorders.

The book begins with a very short and anonymous introduction which outlines Professor Lipowski's career, a career which began in Poland immediately after the Russian occupation and continued in Ireland and Britain before he moved to North America. After working on the Psychiatric Consultation Service at the Massachusetts General Hospital, he set up liaison psychiatry units in Montreal and Dartmouth. Since 1983, he has been Psychiatrist in Chief at the Psychosomatic Medicine Unit of the Clarke Institute and Professor of Psychiatry of the University of Toronto. It has been an eventful life in several ways and it is a pity that Dr Lipowski has not felt able to tell us more about his personal experience. One would like to know more of his life and more of his personal views, even his prejudices. Seven of twenty-seven chapters are new pieces, or more correctly re-written papers, and these help the book to provide an up-to-date view of the current state of liaison psychiatry. There are four sections; Psychosomatic Medicine: Theoretical Concepts; Psychosocial Reactions to Physical Illness (two useful new chapters); Physical Illness and Psychopathology (chapters on epidemiology and organic disorders); Consultation-Liaison Psychiatry.

Professor Lipowski is usually an enthusiast and an optimist and he is a kindly reviewer of research. He can be stern about unsubstantiated speculation but has been reluctant to criticise either the methodology or the very disappointing literature on evaluation. He is somewhat inclined to accept as definitive conclusions what should be regarded as provisional or even speculative. This kindness is probably an inevitable accompaniment of his unrelenting work to establish liaison psychiatry. A harsh scepticism about theory and methodology is also necessary but could not have accomplished much for a very young area of interest.

Much of Professor Lipowski's writings and much

of this book have been concerned with the organisation of services in North American hospitals. The British reader will have quite different anxieties about funding and must also keep in mind that American liaison is providing psychiatric care in a system in which there is little primary care, no psychogeriatrics and no comprehensive catchment area psychiatric services. Very few will attempt to read the whole book but it provides an important and well-indexed reference work by our leading liaison psychiatrist. It is not a textbook of liaison psychiatry but it is the nearest thing that we have. Long may Professor Lipowski continue to scan the medical literature and keep us informed of what is going on.

RICHARD MAYOU, *Clinical Reader in Psychiatry, University of Oxford*

A Manual of Practical Psychiatry. By P. E. Bebbington and P. D. Hill. Oxford: Blackwell. 1985. Pp 405. £19.50.

This large, strong paperback is introduced as a "bench book for the ward or clinic", that is, it is designed to be full of practical information for psychiatrists in training. It is committed to "clarity in assessment and the principle that this should lead to a logical programme of management". Detailed accounts of psychotherapy are deliberately not attempted, but plans of management do discuss such matters as family and social management, and ways of talking to patients.

There are chapters on organic psychiatry, schizophrenia, affective disorders (which comprise mania, depression, anxiety, phobias and obsessional neurosis) and behavioural disorders (alcohol, drug abuse, anorexia nervosa, obesity, insomnia, sexual disorders and personality disorders). Investigations and physical treatments are treated separately in a chapter of their own, and there are helpful sections on the rehabilitation of chronic patients, manipulative patients, violent patients, general hospital psychiatry and "working with colleagues". There is a very full chapter on child and adolescent psychiatry, another on mental handicap, and one on "UK law" (actually British law, as Scottish law is covered but not Northern Irish).

The result is very unusual for a general textbook on psychiatry. There are few discussions of aetiology—none at all for depression, and less than a page for alcoholism. Some ubiquitous old friends such as Kraepelin, Bleuler and Schneider are not mentioned. Instead there are discussions of symptoms and syndromes, and many long lists of headings under which to collect information for assessment of

patients, and for drawing up many-sided plans of treatment. Direct advice is frequently given to the reader on how to handle situations, and specimen remarks to try out on patients. In general the standard is elementary and would be most appreciated by a beginner trainee, but there are also detailed sections where the authors' fondness for lists is impressive and unusually useful (a clear account of admission procedure under Section 47 of the National Assistance Act; 60 syndromes associated with mental handicap; 13 different powers of criminal courts). The flavour overall is strongly of medical psychiatry: this is of course emphasised by the omission of advanced psychotherapy, and can be illustrated by, for example, the 2½ pages on neurosyphilis, the full account of rare physical complications of alcoholism in contrast with only a paragraph on depression and alcoholism, the limitation of psychological testing to tests for organicity, and clinical psychologists doing counselling but not psychotherapy.

There is a mistake on p. 349 concerning consent to treatment under the Mental Health Act: contrary to what the authors state, the patients whose urgent treatment is covered only by principles of common law are those who are informal and those detained under 72-hour sections. Those detained for assessment for 28 days or for treatment are covered by Part IV of the Act. It is unfortunate that the section on Scottish Law is stuck with the transient Mental Health (Amendment) (Scotland) Act 1983, rather than the definitive Mental Health (Scotland) Act 1984, because the numbers of sections are different and, by bad luck, seriously confusing (Section 24 in 1983 was the standard admission procedure for treatment, but in 1984 Section 24 has become the procedure for emergency admission).

Unfortunately there are many flaws in the presentation of the book, arising apparently from poor revision. There are numerous grammatical mistakes, awkward sentences, colloquialisms, terms not explained, and minor inconsistencies between one part of the text and another, which should be improved before any re-issue or new edition.

ANDREW C. SMITH, *Consultant Psychiatrist,
Greenwich District Hospital, London*

Observing the Erotic Imagination. By Robert J. Stoller. London: Yale University Press. 1985. Pp. 228. £20.00.

The central theme of this book, one that Stoller has argued for some time, is that erotic excitement depends upon some measure of hostility towards the opposite sex, and that this arises from early

childhood maltreatment. In their sexual fantasy and behaviour people are seeking (unconsciously) to gain revenge for perceived injustices in infancy, constructing for themselves scripts or scenarios that relate to the critical childhood incidents but which are twisted in such a way that "trauma becomes triumph".

This is a fascinating hypothesis; unfortunately, I do not find it convincing. The idea of a link between sex and aggression is reasonable and does have scientific support, but the dynamic interpretation strikes me as far-fetched. One obvious objection is that it does not explain how non-human animals are sexually aroused; are we supposed to presume that monkeys and rats are also trying to undo childhood traumas in their mating behaviour? Surely it is more parsimonious to adopt the evolutionary view which supposes that male animals are genetically programmed to be sexually aroused by reproductive females, even though the natural course of events may be distorted by brain damage, biochemistry, imprinting errors and learning experiences.

Within this framework, the major facts of sexual behaviour and deviation, which psychoanalysts find so puzzling, are easily understood. For example, it is no surprise that perversion is an almost entirely male phenomenon; females do not have to acquire sex targeting mechanisms in the same way as males. The "dehumanising" of women that is so characteristic of male fantasies and pornography is not for the purpose of gaining revenge against mummy or nanny but is a natural aspect of male novelty-seeking (The Coolidge Effect). Relationship building can be detrimental to the survival of male genes even though it may benefit female genes.

In discussing the origins of male homosexuality, Stoller makes valid criticisms of other psychoanalysts and naive conditioning theorists but the "logic" by which he arrives at his own Oedipal theory is totally unsatisfactory. He cites a Melanesian society called the Sambia in which young boys are taught to fellate older boys in order to gain the masculinity provided by their semen. Since learning theorists would predict that this would lead to near-universal homosexuality in adulthood, yet nearly all Sambia men adjust easily to marriage, Stoller says this proves that childhood intimacy with the mother must be where heterosexuality is learned. If that is so, then why do girls not turn out to be lesbian (since they are equally intimate with their mother in childhood)? And why is the epigenetic (biological) alternative of natural heterosexuality not considered, when it is more parsimonious and at least equally compatible with the data?

Stoller found one Sambia man who did turn out

to be homosexual in adulthood and he explains this as being due to the absence of the father. "It is common knowledge among analysts that one of the contributions to some of the homosexualities is a hopeless, awful yearning for an unreachable father" (p. 128). This typifies what is wrong with this book and psychoanalysis in general. What Freud "says" or Fenichel "believes" is treated as more important than what researchers have found through carefully designed empirical studies. There is a vast scientific literature on sexual arousal and the origins of male sex variation which Stoller ignores (and one of its conclusions is that absent fathers do not produce homosexual sons).

GLENN D. WILSON, *Senior Lecturer in Psychology, Institute of Psychiatry, University of London*

Repertory Grid Technique and Personal Constructs: Applications in Clinical and Educational Settings. Edited by NIGEL BEALL. Beckenham: Croom Helm. 1985. Pp. 407. £22.50p.

According to its dust-jacket, this book has three major aims: (1) to illustrate the use of grids in clinical and educational settings, (2) to demonstrate how grids are being used both in research and practice, and (3) to provide a source book for students and practitioners. It is organised into six main sections. The first gives examples of various clinical applications to which grids have been put and includes articles in which the subjects were children with emotional and behavioural problems, young offenders, women with weight problems, and female agoraphobics. The second section reports studies of the use of grids with people with various disabilities: aphasia, amputations and severe physical disabilities. The third section comprises two chapters concerned with the use of grids in the evaluation of change. Next comes a section of papers demonstrating the use of grids in exploring aspects of interpersonal relationships. The fifth section reports a number of educational applications and the sixth comprises two papers examining the construing by (non-handicapped) adults of mentally handicapped children. In addition to these six sections there is a good introductory chapter on the main approaches to administering and analyzing grids and an equally good final chapter devoted to a critical analysis of the validity of repertory grids.

The 22 British-based contributors maintain a uniformly high standard of writing. The book as a whole conveys the diverse and imaginative ways in which repertory grid methods and personal construct ideas are now being used. My only regret is that the section concerned with mental handicap could not have included something on the use of grids with the mentally handicapped themselves, rather than with their parents and carers. In general, however, this book succeeds admirably in its three main aims.

TOM TRAUER, *Top Grade Clinical Psychologist, King's College Hospital, London*

A Guide to Medical Endocrinology. By TAREK HASSAN. London: Macmillan. 1985. Pp. 269. £17.00 (hb) £8.95 (pb).

The author's premise for this short book is outlined on the inside flap of the front cover. Prof. Hassan's intention was to produce a book primarily for undergraduates which not only incorporated up-to-date facts about medical endocrinology (including all the essential endocrine physiology as an "integral part of an intellectually convincing clinical approach") but also to remind readers of the importance of a patient's non-medical needs. Unfortunately, neither of these commendable intentions are met. It is an extremely difficult objective to combine a comprehensive account of fundamental endocrine principles with a philosophical discussion about their biological and social relevance and still maintain an undergraduate's interest. Moreover, I suspect that few clinical medical students are intellectually adjusted to appreciate, as the author rather laboriously puts it "a perception of the dynamic and multidimensional nature of life". In addition, any text which includes statements such as "... seen through that tragic misorientation, biological realities are just elements to be submitted and subdued or, at best, tolerated grudgingly until they are cured or grown out" will serve to distract and dissuade rather than to inform an enthusiastic mind. The hope that this approach might appeal more to postgraduate readers, particularly those with an interest in the psychological sciences, is again unfulfilled by the nature of too basic an approach and presentation of endocrine detail. Indeed, some chapters are more suitable for sixth form biology text rather than a clinical manual, and highly important information about recent advances is omitted. Disappointingly, there are only a few obscure paragraphs about the psychological and psychiatric elements of endocrine illness. For example the statement that "bodily enactment of repressed material together with body and emotion integration in communication within the group sometimes leads to relevant progress in the management of the problem of obesity" gives little practical guidance for the management of this condition whatever the experience of the reader. It is also disappointing that the author has not included any reference to altered endocrine function in association with psychiatric disease nor the psychiatric manifestations of endocrine disorders, two fields of increasing importance. The author's reasoning behind this book is admirable but I fear that it has merely highlighted an important need. If this should be the case then the book itself will have served a useful purpose, but I cannot recommend it as a necessary reference text for any bookshelf.

P. G. KOPELMAN, *Senior Lecturer in Endocrinology, The London Hospital*

The Ego Ideal: A Psychoanalytic Essay on the Malady of the Ideal. By JANINE CHASSEGUET-SMIRGEL. (Translated by Paul Barrows. Introduction by Christopher Lasch). London: Free Association Books. 1985. Pp. 271. £18.50 (hb), £7.95 (pb).

In the subtitle of this book: *A Psychoanalytic Essay on The Malady of the Ideal*, Chasseguet-Smirgel describes

the essential paradox explored in her essay. By speaking in the same breath of a "malady" (which she states is universal) and of an "ideal" (the ego ideal), an apparent tension is exposed, she argues that this tension can promote psychosexual maturation, but also offer developmental hurdles and cul de sacs. From the outset, however, there seems to be an intention to establish the notion of the ego ideal as a natural force which can function as an internal guide or agency—a maturative force.

This is a scholarly work which is at times acutely intellectual and at others feelingful. Chasseguet-Smirgel refers skilfully to the relevant works of Freud and others. In contrast to Freud, she establishes that a clear distinction is necessary between the function of the ego ideal and that of the superego, and argues this is helpful both in understanding clinical material and in accurately describing developmental processes. Her examples which flesh out this argument, are drawn from art, literature and patients, and give the book a flow and life which was invaluable for the reviewer.

A reading from start to finish will be a not inconsiderable undertaking, but one which is likely to stimulate thought in different and perhaps surprising directions. If a "dip" into this work is made by reading chapters five and eight, the reader is likely to gain access to the core and spirit of the book. A number of her theoretical assumptions may be experienced as arguable. However, Chasseguet-Smirgel has written a challenging and thought-provoking book, which extends psychodynamic thinking in a style which seems to have intended debate.

PETER FULLERTON, *Social Worker, Emanuel Miller Centre for Families and Children, London*

Adolescent and Developmental Breakdown: A Psychoanalytic View. By MOSES LAUFER and M. EGLE LAUFER. London: Yale University Press. 1985. Pp 225. £18.00.

This curiously timeless book, well referenced, by two practising psychoanalysts who are trainers and researchers, is of interest to the student of psychiatric history and presents a clear, though uncritical, limited perspective on adolescence as a theoretical concept. The authors' working framework remains undefined and undiscussed and their book does not offer guidelines to practitioners within any setting with service commitments and limited resources.

Referrals, from unidentified sources, are of men and women of sixteen years and upwards and analysis lasts for periods of three to five years with attendance less than five times weekly being a cause for concern. Money is never mentioned.

The authors, although they emphasise the importance of engaging with the parents of parasuicidal men and women, their only concession to systems theory, work exclusively with their patients and only once is a patient seen first, with her parents, at under sixteen years of age. Hospital admissions are discussed only within the context of the analyst's visits to his patients.

Thus the authors avoid discussion of consent to treatment by under sixteen year olds, nor do they discuss direct analytical work in early adolescence, their theoretical construct of this period being obtained by retrospective

discussion of data obtained from work with young men and women.

Their account of adolescence is relentlessly sexual yet, though some histories indicate the possibility of infra-familial sexual abuse, this term does not appear in the index. "Incest barrier" and "incest fantasies" are indexed but not "incest". Outcome is not discussed.

This is a frustrating book. One might welcome fewer case histories and rigorous, critical discussion of psychoanalytic theory or a contextualised study, with regard to economic reality, or a service for alienated young men and women attending the Brent Consultation Centre. Better still would be a revised book expanded in both directions.

JEAN HARRIS, *Consultant Psychiatrist, Child and Family Psychiatric Clinic, Dunstable, Bedfordshire*

A Method of Psychiatry. Edited by STANLEY E. GREBN, VIVIAN M. RAKOFF and GEORGE VOINESKOS. Philadelphia: Lea & Febiger. 1985. Pp. 475. £32.75.

Faculty members of the Department of Psychiatry at the University of Toronto wrote this book because they could not find a 'good and comprehensive' text which reflected their method of teaching the basis of psychiatry: i.e., 'broadly-based eclecticism'.

On epidemiological grounds, some might question their neglect of the role of the primary care physician in the provision of mental health services, and the scant attention paid to mental retardation (10 pages) and disorders of old age (7 pages). An academic might be pleased by the extensive reference lists but disappointed that more attention was not paid to emphasise research as a component of education.

GREG WILKINSON, *Honorary Lecturer, General Practice Research Unit, Institute of Psychiatry, London*

Child Sexual Abuse within the Family. CIBA Foundation, Edited by RUTH PORTER. London: Tavistock. 1984. Pp. 156. £12.95 (hb), £5.95 (pb).

In dealing with child abuse we are dealing with a matter of public concern. This account of the CIBA Foundation Study Group's examination of the issue of child sexual abuse and its management is a welcome addition to the literature in this area. It forms a basis of good practice for multidisciplinary groups dealing with children and their families with these problems. Its management guidelines are clear and concise for the beginner in the field. It examines the problems from psychiatric, social work and legal standpoints and emphasises the present punitive attitude to perpetrators of child sexual abuse, whilst recommending a more constructive approach within a legal context, a necessary comment in view of the fact that whatever the faults of the present situation, the abuse certainly ceases with the legal consequences of such abusive acts coming to light. It is perhaps less helpful as one might expect in a new field in those grey areas of practice where suspected cases are discussed rather than proven cases.

As in so many works in this area the biggest problem is that we do not know the prevalence of the disorder or its actual acute effects or long-term consequences in any detail. Most accounts are written from a somewhat partisan point of view, a criticism not shared with this particular work. I would recommend it to trainees and their trainers in psychiatry, social work education and the law. The climate of opinion about child abuse, and in particular child sexual abuse is changing. There is a danger that many of the statements made cannot be supported by facts. This book is a healthy corrective to some of the more vehement public statements and should be seen as a reasoned approach to this group of disorders.

L. G. SCARTH, *Consultant Psychiatrist, Royal Hospital for Sick Children, Edinburgh*

Handbook of Clinical Behaviour Therapy with Adults.

Edited by MICHEL HERSEN and ALAN S. BELLACK. New York: Plenum Press 1985. Pp. 732. \$75.00.

Is there an up-to-date book that tutors can confidently recommend as a basic handbook for the increasing numbers of psychiatrists who want to learn more about clinical aspects of behavioural psychotherapy? My hopes were raised on receiving this book, since both editors are well known for an extensive contribution to the behavioural literature over the past 15 years. However, I was soon disappointed.

In the second chapter we are told that systematic desensitisation based on relaxation is the major orthodox behaviour therapy approach to simple phobias. In the next, that most clients with agoraphobia require between six and 18 months of therapy. Both claims are grossly out of touch with orthodox teaching. Instead they reflect the idiosyncratic views of individuals; the first faithfully reiterating the teaching of Joseph Wolpe; accurate 30 years ago but long since superseded; the second, the provocative but unsubstantiated speculations of a worker committed to broadening the base of the subject. This is not a handbook at all. It is a collection of articles which could better be titled "The way we do it in . . . Rhode Island/Pennsylvania State University/Gainesville/New South Wales/ etc . . ." Inevitably there are some first-rate chapters particularly those on the treatment of obsessive-compulsive neurosis; stress and generalised anxiety; cognitive approaches to depression and work and study problems. But this excellence is more than off-set by the rest. It is intensely irritating for the reader of a clinical handbook, 732 pages long, to find many techniques, such as Progressive Muscular Relaxation, Biofeedback, Operant methods for Control of Pain, and Stimulus Control advocated, but then to find no description of how to carry them out. Even worse, as in the case of Autogenic Training is to be referred for further details to an account which is "in press". Many chapters are concerned with speculative accounts of psychopathology rather than therapy, and much of the case material is unhelpful. Feminists will welcome the chapter on sex role considerations, but find it of little clinical relevance.

In such a large book there are surprising omissions. For example, no description of the treatment of habits and tics,

and no mention of sensate focus. The index is woefully inadequate for a book that must aspire to be a reference work.

We need a new handbook which is both practical and basic, and whose editors opt for quality not quantity. This attempt fails on all these criteria.

JOHN COBB, *Consultant Psychiatrist, The Priory Hospital, London*

Psychiatric Nurse Therapists in Primary Care. By ISAAC M. MARKS. London: Royal College of Nursing of the United Kingdom. 1985. Pp. 117. £4.00 (UK), £6.00 (overseas).

Isaac Marks has played a significant and pioneering role in fostering the growth of psychiatric nurse therapists. He has also been tenacious in documenting, analysing and evaluating their roles and functions. This publication, written in collaboration with colleagues, is Isaac Marks' latest contribution to the body of knowledge about nurse therapists. It presents the methodology used in, and the clinical and economic outcomes of, the first controlled study of chronic neurotic patients who were cared for by psychiatric nurse therapists in primary care settings.

The study was conducted over three years: 'control' patients were treated by general practitioners. The nurses were more effective. Health questionnaires to GPs were also used to determine the most suitable catchment population for a nurse therapist. The report suggests 'a population of about 30,000 served by 12 general practitioners'. A national follow-up study of British nurse therapists was also conducted, which indicated that most continue as nurse therapists after training.

An interesting aspect of the research is the cost-benefit analysis which suggests that using nurse therapists is cost-effective for the NHS and the patient. But this is based on nurses' salary levels! Much more rigorous work still needs to be done on cost effectiveness—in all aspects of care within the NHS.

This report must be satisfying to the author for it supports his own commitment and ideology. But if nurses are taking over functions from psychiatrists and GPs, it would be interesting to know how the medical resources saved as a result are used. Do other patients get more and/or better care? Are the saved resources transferred to nursing budgets? Furthermore, does the usefulness of nurse therapists suggest that the expensive training and salary levels of psychiatrists and GPs is an unnecessarily costly burden for the NHS? Perhaps some brave researcher might like to try to find out.

JAMES P. SMITH, *Assistant Director, Long Term and Community Care, King's Fund Centre, London*

Animal Models in Psychopathology. Edited by NIGEL W. BOND. Orlando, Florida: Academic Press. 1985. Pp. 318. \$29.00.

Bond, like editors of similar volumes before him, proposes that an adequate study of human psychological disorders

and the mechanisms underlying them can be made through a consideration of animal models. These he defines as "heuristic devices" from which one extrapolates to the human condition by the argument from analogy. Little emphasis is placed on the "accuracy" of these models: indeed no existence claims need be made for them. Bond argues that an animal model of schizophrenia, for example, need not show characteristics that are homologous with the clinical condition.

These propositions are likely to raise the hackles of those who see little scientific or ethical value in animal experimentation. They leave wide open the criticism that the choice of animal models in psychiatric research is based on vague, arbitrary or simplistic criteria. Although due consideration is given in the introduction and by some of the contributors to the validity of their models and the ethics of their use, the overall case is less than totally convincing.

A more advanced and satisfactory scientific approach is to develop theories based on a synthesis of careful and well-controlled clinical, behavioural, anatomical and physiological observation. Animal studies must then be necessary for the testing of hypotheses, including behavioural ones, that cannot practically or ethically be carried out in humans. Thus there is no further need to speak of experimental preparations as "models". Within this framework, perhaps the best elaborated multidisciplinary theories in psychopathology concern the affective disorders and anxiety/the neuroses, neither of which are considered in detail in this book; although they have been given extensive treatment in other texts. Nevertheless, the most satisfying contributions to this volume pursue their subjects with a strong interdisciplinary approach. Particularly noteworthy are the chapters on obesity, anorexia and the memory disorders.

The canvas of psychopathology painted in this volume is very wide, and there is little overlap in content with other volumes of this general title. Apart from the above topics, the subjects presented range from the teratogenic effects of alcohol and the toxic effects of environmental substances to the aetiology of stress influences on cardiovascular disease and the effects of psychoactive drugs on brain reward processes. In some chapters there is excessive concern with individual experimental methodologies, which, while of interest to scientists in the field, is perhaps beyond the scope of the general overview presented by this volume.

J. D. SINDEN, *Psychologist, Institute of Psychiatry, London*

Advances in Psychosomatic Medicine. Volume 13: Interface between Neurology and Psychiatry. Edited by M. R. TRIMBLE. Basel: Karger. 1985. Pp. 192. \$48.50.

This authoritative volume advances the cause of psychosomatic medicine. Volume 13 of the series selects problems, disorders and systems in the neurological field and presents eight chapters written by acknowledged experts who explore the psychological aspects. Trimble has gathered work on the limbic system, head injury, cerebrovascular disease, multiple sclerosis, movement disorders and epilepsy with chapters on the social environment and behavioural psychotherapy.

The articles are well documented and researched and the bibliographies appended at the end of each chapter and referenced in the text, are wide and exhaustive. This is a mature view of psychosomatic medicine, there is no analytic or dynamic softness but a genuine attempt to link observed behaviour with the emotions experienced and to identify the neurological pathways and the areas in the brain mediating these psychological events.

Gray's chapter on 'Emotional Behaviour and the Limbic System' sets the scene but because the necessary research examples are animal based the view of anxiety presented is at the level of animal behaviour and misses the opportunity to discuss anxiety created in man by moral and spiritual conflicts and relationship dilemmas.

Grant's chapter on the 'Social Environment' moves towards the clinicians interest with consideration of life events and their importance to various neurological crises, to be explored by later authors in more depth. Sims' interesting chapter on 'Head Injury, Neurosis & Accident Proneness' includes a history of the development of psychosomatic ideas and usefully discusses the concepts, before postulating a triangular relationship between his three key conditions.

In the last chapter Cobb gives disappointing views of the limitations of behavioural psychotherapy, but this realistically shows that learning theory must be applied cautiously to man.

The book is well produced in hardback with good quality paper and printing. Medical and psychiatric libraries should stock this challenging volume and will probably wish to examine the other volumes in the series.

DAVID TOMS, *Consultant Psychiatrist & Clinical Teacher, Nottingham University*

Psychiatric Aspects of Chronic Pulmonary Disease. Edited by W. L. THOMPSON and T. L. THOMPSON II, Basel: S. Karger. US\$47.00, SFr. 110.00 DM 132.00

The editors of the book rightly comment in their introduction that although psychological and social problems associated with chronic lung disease are common, little has been written about them. To this extent, this book is welcome, since it provides a source-book of ideas and references for those with a particular interest in this area, even though there appear to have been few advances to justify the series title. It is much less likely to satisfy the wide audience to whom it is said to be directed. I found the sections on medication and occupational diseases particularly interesting but few of the chapters are easy to read and the content is by no means comprehensive as there are no chapters on the nature and assessment of breathlessness, on lung cancer or on hyperventilation. It is also a rather parochial book since six of the eleven chapters are by authors in Denver and another chapter on the important subject of chronic bronchitis is by a writer whose partial view is buttressed by nineteen references, sixteen to himself. It is sad to see this series becoming ever more expensive for ever slimmer volumes. A book for the experts.

RICHARD MAYOU, *Clinical Reader in Psychiatry, University of Oxford*

The Clinical Guide to Child Psychiatry. Edited by DAVID SHAFFER, ANKE, A. EHRHARDT and LAURENCE L. GREENHILL. New York: The Free Press. 1985. Pp. 619. \$45.00.

This book is described by its publishers as *the* definitive source of practical guidance for those who need to deal with the full spectrum of childhood psychiatric disorders. It contains 31 chapters divided into three groups; the treatment of specific disorders, diagnostic techniques, and treatment approaches. Other than Michael Rutter, who writes on autism, all the authors work in the United States, mainly child psychiatrists, but also some psychologists and social workers.

I found myself torn over this book. There is much that is very good and many of the individual chapters are excellent. I could not, however, help comparing it unfavourably with the major text book published in this country by Rutter and Hersov (Oxford: Blackwell. 1984). It is not that one would necessarily obtain a more authoritative account of a particular syndrome in the latter. It is rather that a different approach seems to underlie the two books, approaches which probably reflect the current state of child psychiatry in Britain and the United States. The disquiet which I found myself experiencing over the Shaffer book relates more to where child psychiatry is and where it is going in the United States, rather than the book itself. It reflects a scene where child psychiatry is becoming a uniprofessional medical speciality. Cynically, one might wonder whether this is to justify insurance payments. There can be few psychiatrists in this country who have not at times wished that they could free themselves from

the constraints of multi-disciplinary work and concepts. Reading this book however had a salutary effect on me and I thirsted for a wider bio/psycho/social model for both the origins and treatments of childhood disorders. There are only limited attempts to see the child as a developing organism, fully understandable only in the context of both its family and the wider society in which he or she lives. The narrow view is seen at its most extreme in the chapter on major depression. There is a detailed account of the recognition of the disorder, the use of the laboratory tests and pharmacotherapy. There is no mention of the possibility that the depression could, in a child, be due to abuse by parents or others.

There seems throughout relatively little doubt and insufficient self criticism. This approach is accompanied by a great need to emphasise that child psychiatrists are identical to any other physician who deals with individual patients. For example, child psychiatrists are justifiably criticized for their negative attitudes to physically examining a child, but should a rectal examination really be part of the normal routine?

Having made these complaints, I must again reiterate that there is much to learn from this book. There are for example, useful chapters on stammering, abnormal puberty and the divorcing family. This probably is the best guide to American child psychiatric practice at the present time. It is not, however in itself sufficient to educate the trainee child psychiatrist.

STEPHEN N. WOLKIND, *Consultant Child Psychiatrist, Maudsley Hospital, London*

A HUNDRED YEARS AGO

Gradual Abolition of Restraints

"No longer residing in the Hanwell asylum, and no longer superintending it, or even visiting it, I continue to live within view of the building, and its familiar trees and grounds. The sound of the bell that announces the hour of the patients' dinner still gives me pleasure, because I know that it summons the poorest creature there to a comfortable, well-prepared, and sufficient meal; and the tone of the chapel bell, coming across the narrow valley of the Brent, still reminds me, morning and evening, of the well-remembered and mingled congregation of the afflicted, and who are then assembling, humble yet hopeful, and not forgotten, and not spiritually deserted."

THE BRITISH JOURNAL OF PSYCHIATRY

August 1986

Vol 149

ISSN 0007-1250

Published by authority of
The Royal College of Psychiatrists

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG.*

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al.*, *British Medical Journal*, 7 May 1983, 286, 1489-1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper.**

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full.** Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in *italic* and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form 'Smith, 1971' or 'Smith (1971) showed that . . .'

DURKHEIM, E. (1897) *Le Suicide*. Paris. Translated (1952) as *Suicide: A Study in Sociology*, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. *British Journal of Psychiatry*, **124**, 352-358.

ROUTER, M., TIZARD, J. & WHITMORE, K. (1970) *Education, Health and Behaviour*. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In *Pathology and Treatment of Sexual Deviation* (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80-110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180-210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

The Power of Psychiatry

Edited by PETER MILLER
and NICHOLAS ROSE

Recent mental health legislation, the proposed closure of large mental illness hospitals, and the planning of community psychiatric services have all put arguments about psychiatric ideologies into the forefront of debate.

The authors consider these issues, and their discussions include the role of law in psychiatric reform, the implications of mental hospital closure and attitudes to gender and race. They examine a range of critiques of psychiatry, proposing a framework within which to comprehend its development in the twentieth century.

**THE PROVISION OF MENTAL HEALTH SERVICES IN BRITAIN:
THE WAY AHEAD**

Edited by Greg Wilkinson and Hugh Freeman

ISBN 0 902241 15 X

Pp 197

£7.50

Published February 1986

This unique publication indicates the scope of development in mental health service provision over the past two decades and the major challenges to future progress. It is clear that the contribution made by psychiatrists is crucial. But attention is also given to the views and perspectives of the other necessary participants: regional and district health authorities, local authorities, the provisions that make up both psychiatric and primary care, multi-disciplinary teams, families, and voluntary and other non-statutory care-giving agencies, including the private sector.

Orders with cheques should be sent to: Editorial Office, Royal College of Psychiatrists, 17 Belgrave Square, London SW1X 8PG.

THE UNIVERSITY OF CALGARY

Head, Department of Psychiatry

The University of Calgary and the Foothills Provincial General Hospital have an opening for a joint position of Professor and Head of the Department of Psychiatry of the University and Director of the Department of Psychiatry at the Hospital.

The successful candidate will be an outstanding academic physician with proven administrative leadership, clinical skills and research experience. He/she will relate to the practising community and other affiliated teaching hospitals.

In accordance with Canadian immigration requirements, priority is directed to Canadian citizens and permanent residents.

Applications and nominations should be forwarded by September 30, 1986 to: Dr. M. Watanabe, Dean, Faculty of Medicine, The University of Calgary, 3330 Hospital Drive N. W. Calgary, Alberta T2N 4N1.

آغا خان یونیورسٹی
THE AGA KHAN UNIVERSITY
Faculty of Health Sciences
Medical College

Applications are invited from candidates who meet the requirements for the position of

INSTRUCTOR, DEPARTMENT OF PSYCHIATRY

The Aga Khan Medical College is now in its third year of operation. Its affiliated Aga Khan University Hospital has well equipped teaching and service laboratories and will have 721 beds when fully operational. Candidates applying for this position must have M.B.B.S. and M.R.C. Psych or American Board in Psychiatry or equivalent qualifications. Those intending to pursue a career in Pakistan will be preferred.

Salary and benefits will be offered commensurate with qualifications, experience and level of responsibility. Applications should include detailed résumé, bibliography and names of at least three referees familiar with recent work history. Reply to the Personnel Director, The Aga Khan University, P.O. Box 3500, Karachi-5, Pakistan.

CANADA

Staff Psychiatrist Opportunity
in Edmonton, Alberta, Canada

The Alberta Hospital Edmonton is seeking a qualified psychiatrist with academic and clinical research interests to take charge of our sexual deviancy assessment, treatment and general psychotherapy programs in the Forensic Service.

Reporting to the Director of Forensic Services, you will lead programs designed to fully assess and treat sexual offenders and other patients with sexual deviations, as well as other patients with neurotic or behavioral problems. This service is offered in the context of a comprehensive Forensic Service, with both inpatient and outpatient resources, as well as outreach programs into the various community correctional centres. Clinical research and other academic pursuits will be strongly encouraged.

While Forensic experience is desirable, supervision and training for otherwise qualified candidates can be provided.

The Alberta Hospital Edmonton is a 648-bed fully accredited teaching hospital, affiliated with the University of Alberta. Applicants must satisfy the licensing requirements of the Alberta College of Physicians and Surgeons.

For detailed information on this position, contact Dr. Donald Milliken, the Clinical Director of the Forensic Service at (403) 973-2572.

Detailed applications should be sent to:

Dr. David R. Cornish
Associate Executive Director -
Clinical

Alberta Hospital Edmonton
Box 307

Edmonton, Alberta
Canada T5J 2J7

Forensic Psychiatrist

Alberta, Canada

The Calgary General Hospital has many unique and advanced medical, diagnostic, behavioural science and research programs. This 914-bed teaching hospital is formally affiliated with the University of Calgary.

The Forensic Division, Department of Psychiatry, provides assessment and treatment facilities for the courts and correctional institutions in Southern Alberta.

Candidates must possess Canadian or equivalent qualifications.

While these positions are open to all qualified applicants, in compliance with Canadian Immigration regulations, preference will be given to Canadian citizens or landed immigrants.

Interested psychiatrists are invited to submit a recent curriculum vitae and letter of application to: **Dr. J. Arboleda-Florez, Director, Forensic Division, THE CALGARY GENERAL HOSPITAL, 841 Centre Avenue East, Calgary, Alberta, Canada, T2E 0A1, Tel: (403) 268-9202**

Major Clinical, Teaching & Referral Centre Serving Since 1890.

THE SCIENTIFIC PRINCIPLES OF PSYCHOPATHOLOGY

Edited by
P MCGUFFIN
M SHANKS
R HODGSON

This book is aimed primarily at psychiatrists and clinical psychologists in training and will more than adequately cover their professional and examination needs regarding the scientific principles of their subject. Aspects of recent research in the biological, social and psychological sciences which are most relevant to the practising clinician are also provided in a critical, comprehensive but readable style, making this book a useful reference work for other physicians and professionals from allied disciplines.

ESSENTIALS OF POSTGRADUATE PSYCHIATRY, 2nd Edition

Edited by
PETER HILL
ROBIN MURRAY
ANTHONY THORLEY

Reviews of 1st edition

"... Precision, clarity and scholarship characterise this first textbook of Psychiatry to emerge from the world renowned Maudsley in London."

— American Journal of Psychiatry

"... There are no other serious British competitors ... The book under review provides the most comprehensive, balanced and up-to-date review of knowledge in psychiatry today."

— The Lancet

The second edition of this successful textbook provides extensive coverage of the richness and variety of psychiatry while at the same time integrating psychiatric research findings into a wider body of clinical knowledge. Written by individuals associated with the world renowned Maudsley Hospital *Essentials of Postgraduate Psychiatry* provides a more up-to-date and scientific volume than any existing psychiatric text.

Community Care of the Acutely Mentally Ill*

JOHN HOULT

Deinstitutionalisation is a two-part process: the first involves discharging patients from hospital to the community, which has been done in many countries. The second part—the provision of adequate resources for good community care—has still to materialise almost everywhere. In New South Wales, the inpatient mental hospital population dropped by two-thirds in 20 years, yet the total number of hospital staff increased considerably during this time; on the other hand, in the community, where most of the patients are, there are relatively few staff. This has important consequences: it means that for many patients, their episode of illness has to progress unchecked until it is of sufficient severity for them to be admitted to hospital. When that happens, there will then be enough staff to give them good quality care, so that their symptoms can subside, but afterwards there will again be hardly anyone available to help maintain them and to prevent relapse.

To the staff working in a hospital, a patient's admission is the beginning of a treatment episode, but for the patient and his family, it is the culmination of weeks or even months of increasing suffering which often could have been relieved much earlier, if help had been available. Instead, they may be forced to wait, as their distress intensifies, until the patient's symptoms and behaviour are of such severity that admission to hospital, sometimes even compulsorily, becomes the only option. Hospital admission gives the relatives temporary relief, and alleviates the patient's symptoms and more disturbed behaviour, but before long he returns home; in the case of a patient with schizophrenia, either his apathy or his unpredictability may then again cause concern to his relatives, who have to wait for the next relapse.

A relative of one of the control group patients in our research project described an experience common to many: "The only relief we get is when she is in hospital. She gets violent and doesn't seem to be managed in any other way. She never comes out cured—she gets much better, but it doesn't last more than a month."

Excessive reliance on admission to hospital as the way to deal with the acutely mentally ill involves another problem. Doctors working in hospitals focus on psychopathology: that is what they have been trained to do. Patients and relatives quickly learn that this is what doctors are interested in, and report their difficulties in these terms. This is not to deny the importance of symptoms and signs; patients suffer much distress from them, and it is our duty to offer relief. But many times, the underlying interpersonal stresses which have precipitated the symptoms and signs are ignored, or are not adequately dealt with, and so they persist to precipitate further episodes, which are again dealt with only in terms of psychopathology. Eventually, the patient takes on the role of patienthood, community coping skills get lost, and relatively minor stresses lead to symptoms which lead to further admission. Several research studies have shown that the best predictor of a patient's future use of hospital is the amount of previous hospitalisation he has had (Strauss & Carpenter, 1984; Wynne *et al*, 1978).

In order to interrupt the "revolving-door syndrome", with its high readmission rates, so that resources can be more equitably distributed from the hospital out into the community, where the bulk of the patients are, a means is needed for dealing with the acutely mentally ill in the community.

Review of the published research

The two major changes in the care of the mentally ill—institutionalisation, then deinstitutionalisation—were not done on the basis of research results; it is

*The First Upjohn Lecture on Mental Health Care Delivery given at The Annual Meeting of the Royal College of Psychiatrists 11 July 1985.

only in the past 20 years that controlled studies, comparing one form of service delivery with another, have appeared in the scientific literature. Those studies which compare community alternatives to mental hospital care for the acutely mentally ill have been reviewed by Braun *et al* (1981) and by Keisler (1982). In none of these studies is there any instance in which hospital treatment was superior to the community alternative for the average patient. It could be that, concealed in these aggregate results, are sub-groups who would show marked benefit from hospital treatment. Should further research show this to be the case, it would mean that for some or all of the rest of the patients, hospital treatment was correspondingly less beneficial. The alternative treatments produced outcomes which were equal to, and occasionally superior to that of the control groups, but good outcome appeared to depend on comprehensive and continuous programmes of care in the community. Some of the researchers (Davis *et al*, 1974; Stein & Test, 1980; Fenton *et al*, 1979) followed-up the patients after the experimental treatment ceased; there was little carry-over effect. The improvement of the experimental group patients soon faded, and before long their outcomes were indistinguishable from those of the control group patients.

Stein & Test's study is generally regarded as the best; they had good methodology, excluded the fewest patients from their study, and provided a comprehensive community care programme, delivered in an assertive manner by a relatively large team. Their results were impressive: at each of the four-monthly evaluations during the experimental programme, the experimental group patients were less symptomatic and had better social outcome, compared to the control group. They were not an increased burden on their relatives or to the general community: only 12 out of 65 experimental group patients were admitted to hospital, compared to 58 out of 65 control patients.

Background to the Sydney study

Since 1974, I had worked in a community mental health centre in North Sydney, and had experienced frustrations in my work because of the problems mentioned earlier. In searching the literature for a model for improving the quality of the service, I came across the early reports by Stein & Test. Although Sydney is a city of over 3 000 000 people, and Madison, Wisconsin had only 300 000, their programme appeared to have the necessary ingredients to make it a model for a general method of service delivery, suitable for Australia. However,

the implications of this way of working seemed so important that the original research ought to be replicated, and at a level more in keeping with the level of staffing which could be expected in Australia. Consequently, I obtained a grant from the Australian Government to conduct the research, while the New South Wales Health Department provided extra assistance, in what were increasingly difficult financial times.

The aims of the study were: (1) to demonstrate that it is feasible to treat psychiatric patients in the community as an alternative to mental hospital admission; (2) to show that this can be done without detriment to the patients, their relatives, or the community; and (3) to demonstrate that such treatment costs no more than standard hospital care and after-care.

Method

The sample consisted of those patients who presented voluntarily or were taken involuntarily to Macquarie Hospital for admission over a five-month period, beginning September 1979, and who met the following criteria: (1) resident in the Lower North Shore or Manly-Warringah local government areas of Sydney; (2) aged between 15 and 65 years; and (3) not having a primary diagnosis of drug or alcohol dependence, organic brain disorder, or mental retardation.

Macquarie Hospital is the only state psychiatric hospital serving these two local government areas; it was built in 1959, and has a capacity of 300 patients. It is well staffed, of good standard, and used as a psychiatric teaching hospital for medical undergraduates of the University of Sydney and for post-graduate training by the Royal Australian and New Zealand College of Psychiatrists. In the two areas studied, there is a great diversity of housing—ranging from spacious bungalows to high density multi-storey accommodation; although largely middle-class, it contains significant pockets of poverty and social disorganisation, where many ex-hospital patients congregate in cheap boarding houses. The hospital tends to cater for those of lower socio-economic status and those with the more severe and chronic conditions.

As each patient presented, the Admission Office nurse opened a sealed envelope in which there was a card, allocating him to either the community treatment (experimental) or the standard hospital care and after-care (control) group. No patients who met the eligibility criteria were excluded from the study, so that even the very ill (e.g. acutely psychotic or suicidal) were included. The intake period ended when each group contained 60 patients.

The control group received standard hospital care and after-care, which usually consisted of admission for an average of three weeks to one of two 35-bed wards, each staffed by a fully qualified psychiatrist, three to four trainee psychiatrists, 15 nursing staff, two social workers, one psychologist, and one occupational therapist. Most patients were initially seen by medical staff every day, and

medication was given on the basis of their assessments. The majority were also seen by social workers. The ward treatment programme included large and small group discussions, arts, crafts, work, and sporting activities. On discharge, most patients were referred for after-care to one of the six Community Mental Health Centres in the catchment areas; these are situated in major shopping areas, close to public transport, and after-care of discharged patients is one of their main functions. At the centre, the patient is assigned to a case manager from amongst the multi-disciplinary team; his task is to organise follow-up care, which may consist of regular medication review by a staff psychiatrist, counselling or psychotherapy, as well as individual, social, and family support. However, standard aftercare tends to be of a "passive-response" nature, because the initiative is often left to the patients and their relatives, while home visits are not common. Also, centre staff mostly work normal office hours, and are not available in the later evenings or at week-ends.

For experimental group patients, a member of the Community Treatment Team and its psychiatrist (myself) were called to the admission office. What we did there and later at the patient's home had basically the same ingredients as the management carried out on behalf of the control group patients—only the time frame and the commitment to community treatment were different. We used no special treatments which are not used routinely for patients who are admitted to hospital and later need maintenance care.

First, we made an assessment. Of necessity, this had to be much more detailed than usually happens at hospital; since the patient had a good chance of being taken back to the community, we needed to be sure we were making correct decisions. Relatives and other members of the social network were involved in this initial assessment, where possible. The areas we assessed included: (i) *The presenting problem*—it was important to define this accurately, to be sure of attending to it; while relatives may sometimes say they want help for the patient's delusions or hallucinations, what really has made the situation intolerable is, e.g. the patient's restlessness, or unpredictability, or the potential for violence. Successful community treatment demands that this be confronted from the outset. (ii) *Clinical symptoms and signs*—leading to a diagnosis. A physical examination was carried out by the psychiatrist at the admission office. (iii) *Behaviour*—it was essential to be sure that this would be tolerable to the people who would be in the patient's environment, otherwise community treatment would quickly break down. (iv) *Interpersonal relationships*—the nature and quality of these determined whether the acutely ill patient could return home or needed alternative accommodation to be found immediately. It also alerted us to the need for treatment at a later date. (v) *Social supports and needs*—accommodation, money, and supervision were the immediate needs of all patients treated outside hospital. If they were not available, we would have to provide them. (vi) *Willingness to co-operate*.

Both the patient and his relatives were then actively involved in making management plans: options were examined, and explanations and advice offered. The team was prepared to negotiate to ensure that a plan acceptable to all was arrived at, and that it had a reasonable chance of

being adhered to. These plans included medication (with rapid tranquillisation if necessary), an expectation that the patient should behave as "normally" as possible, decisions as to where the patient was going to go, and how he would be supervised. Patient and relatives were given information about the illness and its expected course, explanation about the Community Treatment Team's methods of working and for the relatives, guidance about how to deal with the patient's symptoms and behaviour. Threats of violence and suicide usually subsided with support, firmness, and medication. It is surprising how often a solution appears for a seemingly intractable problem in a disturbed patient, if one talks to him and his relatives for sufficient time.

If the psychiatrist considered it feasible, the Team then returned with the patient to the community setting, and immediately continued treatment. However, if the situation in the home between the patient and family appeared untenable, the Team took the patient to alternative accommodation, such as a boarding house, and were responsible for his care there. These were patients whose symptoms and behaviour were predominantly the result of disturbed interpersonal relationships, and whose behaviour quickly improved when they were removed from the relationship. This improvement—in a location other than hospital—was important learning for the relatives, helping them to realise the contribution to the disturbance that the interpersonal conflict made, that the patient could control his behaviour and that repeated hospital admission was not a solution to the recurrent disturbances. Initially, staff might stay with the patient for many hours, monitoring his behaviour and the side-effects of medication given, and reassuring patient and relatives. Once the patient became more settled, the staff withdrew, but if necessary, relatives, boarding house managers and patients were encouraged to page us if there was any disturbance or if they were in any way worried, whereupon we would return, if necessary within 30 minutes. The 24-hour availability greatly reassured the relatives and the managers. We had previously arranged with certain boarding house managers for permission to use their facility for our patients; once they knew that help would be quickly available and we did not expect them to tolerate disturbed behaviour, they readily accepted our patients (and their money) and were helpful supervisors. The Team visited frequently for the first few days and even took the patient out with them for some hours to give relief to families. The medication was adjusted frequently, according to the patient's response, and necessary clinical investigations carried out at this stage. In most cases, quite a strong and enduring treatment alliance was formed over the first few days; patient and relatives learned to regard the illness in quite a different light, and learned new ways of managing it. As quickly as possible, the patient was expected and encouraged to be responsible for himself and resume normal duties. Where necessary, staff accompanied the patient on tasks of community living in order to assess, supervise, and train him in these tasks in the natural setting. For most patients, these activities by the staff soon decreased as the patient became less psychotic, but for those with chronic, severe handicaps, they continued on an on-going basis. Staff assertively

trained patients in adequate hygiene and grooming, as well as in the use of community facilities such as transport and supermarkets, day centres, and sheltered workshops.

Subsequently, the Team remained responsible for all experimental patients. In some cases, patients had a recurrence of their symptoms during the study year, but the Team was usually contacted early, and were able to intervene quickly and deal with the symptoms and the associated problems without needing to admit the patient to hospital.

Some acutely psychotic patients did need admission. These were patients who either fell asleep when given tranquillising medication at the admission office and so stayed in hospital overnight, or who refused initially to co-operate with treatment, and so had to be admitted so that they could be compulsorily treated. After two or three days, most agreed to co-operate, and so were discharged. A few chronic patients had an exacerbation of symptoms and were too disorganised in behaviour to be tolerated outside hospital; these patients needed longer stays. Patients who were admitted remained in the experimental group; they were supervised in hospital by the Community Treatment Team psychiatrist, and on discharge, were offered the same treatment as those who were not admitted.

The Community Treatment Team for the 60 patients in the study consisted of three psychiatric nurses, two social workers, one occupational therapist, one psychologist, and one part-time psychiatrist—none of whom had had previous experience with this kind of treatment programme. The staff were rostered on duty for two shifts every day: one staff member remained on call from 11.00 p.m. till 8.00 a.m. Training consisted mostly of role-plays of likely situations to be encountered at the admission office and at patients' homes; a problem solving approach was used. There were formal lectures on medication and recognition of its side-effects, and on systems and family theories; staff also familiarised themselves with the area and its resources. Two or three week full-time training seems to be adequate for professional staff.

Assessments were carried out at presentation and 1,4,8, and 12 months later by two research psychologists, who were independent of the Community Treatment Team. Structured questionnaires were designed to measure a wide range of problems and attitudes, both from the patient's perspective and that of his relatives. Clinical status and outcome were measured by, amongst other scales, the Present State Examination (Wing *et al*, 1974), while a cost-benefit study was also done.

Results

At baseline, there were no significant differences between the two groups on any of the characteristics measured. Three-quarters of the patients had been previously admitted to a psychiatric hospital, and almost one-third had spent one year or longer there. Three-quarters were diagnosed as suffering from one of the functional psychoses, and one-half suffered from schizophrenia. There were few (6%) neurotics. About 60% of both groups presented as involuntary patients. At 12 months, 88% of the experimental and 84% of the control group patients

were interviewed, while of the relatives, 80% and 78% respectively were interviewed.

The full details have been presented in the major report of the study (Department of Health, N.S.W., 1983a); only the main findings will be presented here. Tables I and II show a highly significant ($P < 0.001$) difference between experimental and control group patients in terms of number of admissions and length of stay in psychiatric hospitals or clinics (public and private) during the 12-month study period. With one exception, experimental group patients who were admitted for one week or longer were chronic patients (i.e. they had previously been admitted for one year or longer). Control group patients spend an average of 53.5 days in psychiatric hospitals; experimental group patients spent an average of 8.4 days.

Community treatment achieved a superior clinical outcome. At 12 months, PSE results showed that experimental group patients were significantly lower on the total score and on each of the four sub-scores (Table III). For both groups, psychotic symptoms had greatly declined since baseline, but non-specific neurotic symptoms were still prevalent, and 29% of the experimental and 43% of the control group patients still had sufficient symptoms for a diagnosis of psychosis.

Both patients and their relatives considered community

TABLE I
Number of admissions to psychiatric hospitals or clinics during 12 months study period

	Experimental (n = 53)	Control (n = 47)
None	32 (60%)	2 (4%)
1	17 (32%)	21 (45%)
2	2 (4%)	17 (36%)
3	1 (2%)	5 (11%)
4+	1 (2%)	2 (4%)

TABLE II
Length of stay in psychiatric hospitals or clinics during 12 months study period

	Experimental (n = 53)	Control (n = 47)
Not admitted	32 (60%)	2 (4%)
Less than 1 week	14 (26%)	11 (23%)
1-2 weeks	0 (0%)	6 (13%)
3-4 weeks	3 (6%)	5 (11%)
5-6 weeks	3 (6%)	8 (17%)
7-10 weeks	0 (0%)	4 (9%)
11-15 weeks	0 (0%)	6 (13%)
16 weeks or more	1 (2%)	5 (10%)

TABLE III
Mean Present State Examination total and sub-scores at baseline and 12 months

	Baseline			Twelve months		
	<i>Experimental</i> (<i>n</i> =58)	<i>Control</i> (<i>n</i> =57)	<i>Sig</i>	<i>Experimental</i> (<i>n</i> =52)	<i>Control</i> (<i>n</i> =46)	<i>Sig</i>
Mean total PSE score	30.5	30.9	NS	9.8	15.4	$P<0.001$
Mean DAH (delusional and hallucinatory syndromes)	8.2	8.4	NS	1.9	4.0	$P<0.001$
Mean BSO (behaviour, speech and other syndromes)	7.0	7.3	NS	2.0	3.1	$P<0.001$
Mean SNR (specific neurotic syndromes)	4.5	5.0	$P<0.01$	1.4	2.4	$P<0.001$
Mean NSN (non-specific neurotic syndromes)	10.5	11.6	$P<0.01$	4.2	6.0	$P<0.001$

TABLE IV
Summary of patients' and relatives' satisfaction with care received during the 12 months study period

	<i>Control*</i> (%)	<i>Experimental*</i> (%)	<i>Sig</i>
Patients very satisfied with advice and information	29	60	$P<0.01$
Patients very satisfied with support and help	33	65	$P<0.01$
Patients very satisfied with amount of supervision	12	56	$P<0.001$
Patients preferring admission to community treatment	25	12	NS
Relatives very satisfied with support and help patients received	28	83	$P<0.001$
Relatives very satisfied with the amount of supervision patients received	30	85	$P<0.001$
Relatives who themselves received enough support and information	39	88	$P<0.001$
Relatives coping better during study year than before	28	70	$P<0.001$
Relatives preferring hospital admission to community treatment	35	2	$P<0.01$

*The numbers were 53 experimental and 48 control patients and 48 experimental and 47 control relatives.

treatment to be significantly more satisfactory and helpful than standard hospital care and after-care (Table IV). The majority (80%) of experimental group patients who were not admitted to hospital were pleased and grateful about it; only 30% of control group patients were pleased and grateful about being admitted to hospital, whereas 39% were upset and angry about it. Nearly all relatives regarded the community treatment experience positively; they considered it to be significantly more helpful to the patients and themselves than standard hospital care and after-care (Reynolds & Houlst, 1984). A separate analysis of the responses of the 54% of relatives who lived with patients indicated that, for them, community treatment was no less satisfying and helpful: a relative of an experimental group patient said—"I like the idea that help can be reached any time day or night. I feel I am sharing the load. Mental hospital terrifies him and now he knows that he won't be admitted, he's not afraid to admit when he is in need of treatment, so he gets treated quicker and does not have such a severe relapse."

Community treatment did not result in more legal offences or police contacts, but it was not as effective as standard care in reducing the number of suicide threats and attempts. However, none of the community treatment patients, but two of the controls, died during the 12-month study period. A brief survey of all patients, 3½ years after presentation, revealed that seven control group patients were dead: three had definitely committed suicide, two had drowned (possible suicides), and two died from natural causes. No experimental group patients were dead at that time.

For two sub-groups of patients, the data were analysed separately. Firstly, for those given a diagnosis equivalent to schizophrenia by the Catego Programme of the PSE, the results mirrored the results of the total sample (Houlst & Reynolds, 1984). Secondly, those patients who had never had a psychiatric admission prior to entering the study: of 11 in the community treatment group, only four were admitted during the 12-month study period, none for longer than three days, and none were re-admitted during this time. In the control group, 11 out of 12 patients presenting for the first time were admitted and five (42%) had two or more admissions during the study year. Although these numbers are small, it could be hypothesised that the prevention of that first psychiatric admission may well prevent a patient starting on a career and identity as a mental hospital patient.

During the 12-months study period, the average treatment cost (public and private, direct and indirect) for each experimental group patient was A\$4,489 and for each control patient A\$5,669; i.e. standard hospital care and after-care cost 26% more than community treatment. For experimental group patients, 81% of the treatment costs were incurred in the community, mainly the cost of the Community Treatment Team, but only 7% of the treatment costs to control patients were incurred in the community. Cost of treatment in Macquarie Hospital accounted for 79% of all treatment costs incurred by control patients, and closely approximated the total costs incurred by the Community Treatment group (Cass & Lapsley, 1983).

Discussion

Our findings confirmed our aims: it is feasible to treat most psychiatric patients in the community as an alternative to mental hospital care. It does not transfer the burden to the community; it is preferred by patients and relatives, and it is possible in this way to get a better clinical outcome for less cost. This latter fact indicates that the effective ingredients lay in the mode of treatment rather than the amount of resources. While improvements in the quality of standard hospital care and after-care (e.g. more community staff, more support to relatives) may have resulted in improved outcome or more favourable attitudes, it would have required even more resources, and hence would increase the cost differential between the two modes of treatment.

The research finding that the amount of previous hospitalisation is the best predictor for future hospitalisation has been called a circular one; and that these are the most severe illnesses which actually do require the most hospital care. I think this explanation is only partly true; the finding from our study that amongst the sub-group of control patients with no previous hospital admissions there was a 42% re-admission rate within 12 months and no re-admissions from the experimental group gives credence to the idea that once a patient is known to have had a psychiatric admission he is much more likely to be re-admitted. Unfortunately the numbers in the sub-group are too small for definite conclusions to be drawn.

The Stein and Test study and our replication of it were the two studies which had the most comprehensive and continuous programmes of care in the community; they also were the ones with the fewest exclusions of patients, and included dangerous, suicidal and acutely psychotic patients. Quite a number of these could be managed safely in the community, but there were still some in both studies who could not. Clearly, hospital care is still needed for a few patients, though many fewer bed days are required than at present.

In his Annotation on "Alternatives to Psychiatric Hospitalisation", Tantum (1985) puts the view that one of the main lessons from this research "is not that hospital admission is no good but that conventional after-care could be improved," and that brief admission followed by intensive community support, such as was available to patients in the experimental projects, would be equally satisfactory. These statements are the common response of hospital-based workers to the challenge to what Tantum calls their "traditional hegemony". Currently, the hospital is the focal point of most psychiatric services; the highest status is accorded to it,

academics are attached to it, the bulk of the staff work there, and most of the funding is spent there. Domiciliary assessment is often merely a funnel to hospital which, in the minds of most professionals, is the place where any treatment of importance takes place. Even the word "aftercare" implies just that; care *after* the main treatment has taken place. Although research has pointed out the continuing high relapse rate, and has identified family and psycho-social factors and non-compliance with medication as being responsible for these relapses, services are still organised to treat the advanced relapse, rather than to prevent the relapse occurring or to treat it vigorously in its early stage. If conventional aftercare were to be improved on a nation-wide scale so that the problems of deinstitutionalisation could be rectified and good care was available for all, the financial cost would be very high. Governments in all countries have baulked at it. Extrapolating from our study, it would mean doubling the cost of services unless there was a corresponding decline in the use of the hospital. Whether brief hospital admission followed by intensive community support would produce an improved outcome without being prohibitively costly remains to be demonstrated. I personally doubt it; given human nature, I think the hospital service would soon build up again if it remained the central part of the service.

The studies on alternatives to psychiatric hospitalisation tell us, in essence, to change our focus from the patient in *our* hospital to the patient in *his* community. If our psychiatric services are organised to ensure that most of the staff and most of the funding are directed towards the patient in his natural environment, then help can be provided early, can be intensive and extensive, and can be capable of producing an outcome as good as, or better than what is currently available, and at about the same cost.

The problems of deinstitutionalisation are in large part due to our present imbalance in service organisation. Most patients in the community are unsupported most of the time; most staff are in the hospital treating episodes, many of which could have been prevented or aborted. The perils of both deinstitutionalisation and institutionalisation can best be addressed, as Tantum concludes, "by considering hospital care . . . as one of a range of carefully judged, social interventions which psychiatrists can deploy in assisting the patient to lead his life as little hampered by his illness as possible." This will mean re-focusing our service orientation and surrendering the "traditional hegemony" of the hospital.

From our experience and that of others, the following principles of care seem to be important ingredients: (1) the intensive nature of the help at the beginning; the 2-4 hours spent at the initial interview and the frequent visiting or even continuous period spent with the patient and his family during the first few days helped form a therapeutic bond between the patient, family, and staff. It also relieved the burden on the family, and in many cases allowed them to resume normal routine. (2) A willingness to involve actively both patient and relatives or care-givers in the management programme and to provide them—where appropriate—with information, support, guidance, and counselling. (3) Consistent care by the one team. (4) A personal case manager, who accepted responsibility for ensuring that the patient's needs were met and for co-ordinating with other agencies providing service. (5) A preparedness to go out to the patients and their relatives assertively, but without being unnecessarily intrusive. (6) Help with practical problems of living; this included the teaching of living skills at the place where the patient needed to use them, so that the problem of learning not generalising from the hospital to the community (Test & Stein, 1978) was avoided. (7) A service available 24 hours a day, easily accessible, mobile, and rapidly responsive, so that patients and relatives feel secure, and early intervention can prevent relapse. (8) An on-going and extensive service, rather than a time-limited service.

All staff on this project quickly came to prefer this way of working. It was more satisfying and meaningful than their previous work; two have since set up, and are still running, crisis teams in other parts of New South Wales. Staffing levels for a crisis team which is part of an on-going community service cannot be easily determined from our study, as methodological requirements for research projects create a degree of artificiality, e.g. while one psychiatrist can be on-call continually for the limited number of patients in the project, and for the limited time of the project, he cannot continue indefinitely like this. A mobile crisis service should be part of a network of community-based support services, and either the latter services pick up on-going care once the crisis has resolved, or the crisis service is manned by regular community mental health staff on a rostered basis. At least two staff should be available for the crisis service for two shifts seven days per week, and fixed rosters are preferred by staff so that they may organise their private lives. Psychiatric cover for the crisis service should come from the consultant and trainee psychiatrists covering the rest of the catchment area service.

In New South Wales, a Department of Health (1983b) inquiry into psychiatric services has recommended that, as a matter of policy for State Government services, the highest priority be given to the development of adequately staffed, community-based teams throughout the state to provide crisis care, treatment, and rehabilitation for the severely mentally ill. The criteria for these services are similar to those mentioned above.

The State Government has accepted and is now implementing the recommendations, transferring resources from the mental hospitals to the community for this purpose.

Acknowledgement

The excellent work of my colleague, Ingrid Reynolds, throughout the project described is gratefully acknowledged.

Review Article

Witchcraft and Psychotherapy

J. S. NEKI, B. JOINET, N. NDOSI, G. KILONZO, J. G. HAULI and G. DUVINAGE

Belief in witchcraft, which serves a variety of social functions and personal defences, is bound to emerge in psychotherapy with individuals from a culture that holds such beliefs; endeavouring to understand it can open up new therapeutic possibilities. The nature of witchcraft, the profiles with which it intrudes into therapy, and the socio-psychological functions it fulfills are considered. Referring such patients to witchdoctors is morally unjustifiable, but the witch-doctor's folk-image provides a floating transference, around which the therapeutic relationship can be built. In dealing with witchcraft-ideation, understanding is based as much on cultural as on personal empathy, and to enhance its relevance, therapy may appropriate some of the functional dynamics of the witchcraft system into its own therapeutic manoeuvres.

Increasing emphasis on availability and accessibility of mental health services to all populations in the developed world has brought into focus the centrality of racio-cultural interests. The training of the Western therapist does not equip him adequately to empathise with the attitudes and beliefs of cultural minorities, and it is being increasingly felt that white therapists should have some practicum and internship experience in black communities (Butts, 1972; Vontress, 1974). This is tenable *mutatis mutandis* with regard to any ethnic minority anywhere, and in developing countries, many of the strategies and techniques of Western psychiatry, especially those of psychotherapy, do not seem to be relevant to their belief systems (Pande, 1968).

Witchcraft-ideation 'stands out' prominently among such beliefs. A Western-trained psychiatrist experiences much difficulty in dealing with it, and therefore tends to dismiss it as 'one of those primitive superstitions'. By doing so, he may block the opportunity to discover the dynamics that might be causing, shaping, elaborating, or repressing symptoms. In therapeutic work, we have often encountered witchcraft-ideation, and believe that if one tried to unravel its dynamic significance, new therapeutic possibilities might emerge.

The authors are a multi-national team, engaged in psychotherapy with the Bantu population. Three (NN, GK and JGH) are native Tanzanians; JSN is an Indian psychiatrist who has worked in Africa for nearly six years; BJ a French national who has been a priest cum psychologist for 20 years in Tanzania;

and GD a German clinical psychologist, working in Tanzania for over two years. We, therefore, bring together a variety of cultural perspectives—Western, Eastern, and African. By virtue of cultural contrast the non-Africans among us can more easily identify culturally significant phenomena in their Bantu patients, and offer hypotheses about them; their local counterparts provide the corrective feed-back from their indigenous vision.

What is Witchcraft?

Reviews of witchcraft are already available (e.g. Evans-Prichard, 1937; Robins, 1959; Parinder, 1963), so that we will only try to highlight those aspects which seem most relevant to our discussion. There are some differences of opinion about the definition: while most lexicographers (e.g. Little, 1956) do not distinguish it from 'sorcery', many anthropologists in fact do so. Evans-Prichard (1937) and, following him, Middleton & Winter (1963), Beattie (1964), Harwood (1970) and Mair (1974) among others, (especially those who have worked in Africa), make a distinction between the two terms. Witchcraft is defined as a 'mystical and innate power which is used by its possessor to harm people'; while sorcery is defined as 'evil magic against others' employing herbs, medicines, charms, etc. Yet there are other anthropologists, e.g. Raum (1967) who use the two terms interchangeably; in fact, these have been employed in a thoroughly chaotic manner, even within a single symposium

(Middleton & Winter, 1963). Many African tribes make a linguistic distinction between the two concepts: Kiswahili, for example, has the expression *ulozi* for witchcraft and *uchawi* for sorcery, while the same distinction is made by the Akan, Ashanti, Azande, etc. However, we propose to subsume both these terms under the rubric 'witchcraft', because both represent culturally appropriate responses, which function as alternatives in the same kind of situation (Farke, 1962), co-exist frequently in the same society (Harwood, 1970), and provide habitual explanations for misfortune (Lewis, 1976).

Witchcraft is a theory of causation: it does not deny natural or empirical causes, but seeks supernatural ones behind them. Two questions can be asked in the context of every misfortune: 'how' did it happen?, and 'why' did it occur at all?. The 'how' is answered by empirical observation; the 'why', *inter alia*, by witchcraft. Even if our scientific understanding of the 'how' increases, it will still not be able to dispose of the 'why' of a misfortune. Hence, the two beliefs may easily co-exist.

Figure 1 illustrates the place of witchcraft in the system of causality. Witchcraft shares this hierarchical position with sorcery, cursing and the evil eye. A witch-dominated world is essentially a closed world, where persons and human relationship and more important than material good, where everybody is somebody, and where moral identity prevails and group values receive emphasis. Two kinds of person threaten this closed world—the deviant and the alien—who are the sources of evil, since they may well be witches.

A witch is believed to carry out her art in secret, especially at night. The practice is socially proscribed in almost all African tribes, and anyone discovered practising the black art, is punished, ostracised, or even killed.

As a system, witchcraft can absorb empirical causality, and can also absorb and explain many of its own failures by virtue of what Evans-Prichard (1937) called 'secondary elaboration on belief'—successes will be remembered and failures explained away. An analogous situation can be discerned in psychoanalysis—if you accept an 'interpretation', well and good; if you don't, 'denial' is presumed to be at work. "Direct assault on a closed system of ideas is not easy, since the system absorbs the attacks and converts them to strengthen itself" (Gluckman, 1966).

Witches and anti-witches

The African witch is quite distinct from the European version in having no truck with the Devil

FIG. 1 The place of witchcraft in the system of causality. The witch sits on the borderlands between the two, and is human in form (thus subject to intutional causality) but imbued with supernatural power (and hence wields noumenal causality).

and not holding Sabbath assemblies. In certain tribes, however, there is something like a Sabbath assembly, where the 'witch' is believed to ride snakes and hyenas. In fact, an African witch may not even be aware that he/she is one, until beginning to bring misfortune to those wished ill. It is the use of witchcraft, and not its mere possession which is despised by African tribes.

Three types of witches have often been distinguished: (i) *Stereotyped* or 'night' witch, with a cosmic dimension of evil, flouting all the rules governing property, sex, law, and decency. (ii) *Presumed* known about and feared by everyone, but somehow left alone. These include unpopular, asocial, arrogant people, as well as those with a staring gaze, with abnormal and ugly features, of mixed descent, and very advanced age (who have lived so long 'by virtue of witchcraft'). (iii) *Accused* indicted to have caused a misfortune; generally an avowed enemy or rival of the accuser.

In fact, these are not three different types of witches, but three stages of the process of witch-naming. Since witchcraft is not necessarily a voluntary act, and can even be exercised in sleep, without the person knowing it, no account is taken of the accused's denial of guilt or of any defence. Advantage always lies with the accuser.

The antiwitches or witchdoctors are benevolent witches, whose powers are superior to those of the malevolent, whom they can contain and control; through the power of oracle or divination, they can identify the malevolent witch responsible for a given act. They can also exorcise an evil spirit through their mystical power, ritual, or medication. They may be able to forewarn through foretelling oracles, and even intercede between the mortals and the spirit world; they have a medley of procedures at hand—rituals, spells, charms, potions, and even jugglery.

There is no clear distinction between a witch and an antiwitch, except intentionality. However, the witch-doctor is generally an intelligent person, competent in ritual knowledge, and convinced of the power of witchcraft and of his own powers. As he can bring harm to a man who is doing a moral wrong, he is held in great awe. In most of Africa, witchcraft is believed in not only by the uneducated and semi-educated, but also by well educated people—even doctors and scientists.

Emergence into Therapy

With the African, witchcraft ideation is a pervasive background belief which turns into a cognitive reality in times of stress. It may well be present at the very outset of therapy, having been generated prior to it, or may be unleashed by the therapeutic process itself. It may, at times, even be occasioned by the therapist who, on account of his appearance and demeanour, gets identified with the witch-doctor, or it may be part of the symptomatology of mental illness itself.

It generally emerges in one of the following ways:

(i) *As an explanation for all kinds of misfortunes* e.g. frustrations of life, failure in love, lack of success in business or examinations, or losses or deprivations of any kind. It may be spontaneously verbalised or brought out by encouragement. Sexual difficulties such as impotence are especially prone to be explained as caused by witchcraft. Prince (1966) reported that Yoruba males often dream of an assault against their genitals; alternatively, a witch is believed to have used an individual's penis in order to consort with his wife or with another woman, and then returned it in an altered and functionless form. Women consider witchcraft to be the prime cause for drying up of their breasts, for frigidity toward their husbands, and for sterility.

Witchcraft may also be a preferred explanation for bodily sensations such as the paraesthesiae of peripheral neuropathy and the phantom limb phenomenon after an amputation. It may also be the presumed

cause for physical or psychic illness, ruptured social relations, physical disaster, and natural catastrophe. (ii) *As a cause of the presenting symptomatology itself.* Actual or presumed bewitchment often generates intense anxiety and apprehensive foreboding. The physical and psychic symptoms that it produces only tend to confirm the suspicion and power of witchcraft, and further strengthen apprehension: a vicious circle sets in, and apprehension spirals up. Bewitchment anxiety, if unrelieved by traditional countermeasures, or if such measures are unavailable, may develop into "malignant anxiety" (Lambo, 1962), which may even lead to death, in a way that can be likened to 'voodoo death' (Canon, 1957). Occasionally, there is 'boomerang witchcraft': that practised on someone else having failed, the attempter begins to believe that the other person has superior powers, and might play counter-witchcraft. Patients with anxiety generated by suspected or boomerang witchcraft often look pale, sickly, and terrified, and are often perplexed or even confused. They verbalise their terror characteristically as 'a ghost has hit my heart'; 'a dragon is choking my breath', 'my life is being sapped away', etc. The onset is often traced back to some 'unusual' event, e.g. the skin of a snake lying outside one's door, or seeing a dead body in a dream.

(iii) *A symptom of illness.* The content of delusions is known to be subject to pathoplastic cultural influences and amongst people who believe in witchcraft, delusions of witchery are commonplace. The mentally ill, as much as the healthy express themselves in the idiom of their culture. A paranoid patient in the West may talk of people harming him through radio-waves, microwaves, or laser beams, while one from a witchcraft-believing culture will complain in witchcraft terms. In the latter, the complaint of witchcraft as such may not be clinically significant, but the embedded complaint of being persecuted is (Leighton, 1982). Basher, a Sudanese psychiatrist, said that to diagnose delusional witchcraft ideation, you have to "look for the knight's move" (Savage *et al*, 1965); in other words, there is some oddity which other members of the patient's cultural group sense in the patient, and do not consider to be identical with familiar witchcraft ideas. An astute clinician is generally able to distinguish between culturally prevailing non-delusional fixed beliefs and the delusional symptomatology of a psychosis, expressed in witchcraft terms. The delusional ideation of witchcraft is often mistaken as superstition, but a distinction has to be made between simply 'superstitious' and 'basically delusional' beliefs. Table I presents the distinguishing features of the two.

TABLE I
Differences between delusional and non-delusional witchcraft ideation

Non-delusional Witchcraft Ideation	Delusional Witchcraft Ideation
1. Little accompanying symptomatology – at most, symptoms of anxiety and apprehension, which seldom assume psychotic dimensions.	Symptoms of a psychotic disorder almost always accompany. These often include hallucinations and loss of contact with reality.
2. Symptoms generally subside after a diagnostic divination and prescribed corrective measures.	Symptoms remain unabated, even after a diagnostic divination and observance of prescribed corrective measures.
3. Accompanying behaviour defensive and guarded; often considerable reticence in expression witchcraft ideas.	Accompanying behaviour may openly be vindictive and hostile; e.g. acting on hostile impulse and assaulting the person who is suspected to have effected witchcraft.
4. Considerable acceptance of the patient's ideation by his social milieu.	Only a partial and often sceptical acceptance of his ideas by the patients' family and others around him.
5. Ideas seldom, if ever, get generalised and systematised, but may become vague and dissipated.	The ideas often tend to get generalised as well as systematised.
6. Ideas of witchcraft seldom appear suddenly. 'Evidence' accumulates over a period of time before crystallising into definitive witchcraft ideation.	Witchcraft ideas may suddenly descend 'like a bolt from the blue', thereafter showing secondary elaboration.
7. Ego-syntonicity of the ideas comparatively less rigid.	Ego-syntonicity is firm and rigid, and unamenable to influence.
8. Patient usually shows considerable concern about having been bewitched.	Patient may show a weird unconcern with his witchcraft-delusions, much like 'double orientation'.
9. Social withdrawal is circumscribed, i.e. only from the suspected person.	May be much more generalised social withdrawal than from the suspected person alone.

(iv) *As feigned or malingered.* The patient is consciously aware that no witchcraft has actually been practised, but feigns it, and imputes it with clandestine intention to some specific person; i.e. there is no real victim of witchcraft, but only a victim of imputed witchery. Such behaviour is indulged in generally for the purpose of 'distancing' from a person whom the patient finds emotionally offensive, but socially inescapable.

Sociodynamics

(a) *Instrument of moral suasion*

Witchcraft belief is a potent instrument of moral influences and checks members of the community from transgressing its moral codes. The fear that a transgression, even an inadvertent one, can lead to

punishment through witchcraft keeps people from infringing taboos and moral sanctions.

It is not unlikely that 'guilt', 'shame', and 'fear of witchcraft' are prototypes of one another, in different cultural settings. In cultures with 'internalised' moral controls, *guilt* feelings are unleashed by moral transgression. In other cultures, where social controls are, by and large, external, *shame* is generated. In yet others, where such controls are supposedly exercised by 'supernatural' forces, *fear of witchcraft* and allied phenomena (hex, sorcery, etc.) tends to appear.

(b) *Control of aggression and ambition*

It is believed that one who attains any 'glaring success' comes 'into the people's eyes'; others

become jealous of him, and may try to undermine his success and achievement. Therefore, people must try to keep their ambitions under check, and not outbid their neighbours, or it will evoke jealousy, which, in turn, evokes witchcraft—'jealously comes first, witchcraft later'. A person who is exceedingly successful in life is suspected of possessing witch-power himself, while other aggressive tendencies are also believed to evoke counter-measures in the form of witchcraft.

The witch as a scapegoat also becomes an outlet for repressed aggressiveness of the group. In general, Bantu society represses aggression, permitting this, at best, to be symbolically expressed in joking relationships, and dances. However, it can occasionally gain a real hold upon a socially acceptable target: a thief, if caught, is often beaten to death on the spot, and so is a person accused of witchcraft.

(c) Solving relationship difficulties

Interpersonal relationships, especially within the extended family, are fraught with tensions of all kinds, which may exist between relatives who cannot be informally distanced. Imputation of witchcraft brings about a formal distancing, where this had not been possible—generally within the family—but it may also be employed for distancing real or suspected 'enemies'.

(d) Guide for action in disaster

In times of disaster, an oracle or divination is resorted to, which not merely serves to diagnose the presence (or otherwise) of witchcraft as the cause of disaster, but may also prescribe counter-measures to be taken. It thus provides guidance for action and thereby mitigates suffering.

Psychodynamics

(a) Ego-defence mechanism

Witchcraft is a socially accepted explanation, not simply for personal misfortune, but also for failures and weaknesses: a student failing an examination, a businessman incurring losses from indiscreet investment, a drunk driver causing an accident, a hunter unable to shoot any game may all impute their 'bad-luck' to witchcraft. Goldschmidt (1977) gives an instance of a Sebei young girl who 'cried the knife' when she was being circumcised for her initiation, and refused to let the operation be completed until she was held down forcibly; he had expected that she

would have remorse over her behaviour and go into 'deep depression and self-hatred'. However, nothing of that sort happened, for the culture had provided her with an institutionalised ego defence: she knew who had made her 'cry the knife'—it was a man whose advances she had rebuffed, and who had performed witchcraft. Witchcraft ideation, as a coping mechanism, enables one to shelve responsibility for personal failings, and is a reason why feelings of guilt are so rare among believers in witchcraft.

It may also involve the dynamic of scapegoating. If witchcraft imputations are readily accepted by one's social milieu as a semi-serious alibi for personal failings, then witchcraft acts as a buffer against social sanction. However, if the imputation is taken seriously, and leads to a witch-hunt, it can end in catastrophic scapegoating.

(b) Institutionalised distrust and jealousy

Behind the ideation of witchcraft often lie distrust and jealousy, both of which appear to prevail in a veiled way throughout the social substratum, but during times of stress, these become unveiled in the form of bewitchment imputations. Alternatively, an individual presumes himself to be the victim of witchcraft because he disturbed the social harmony, by getting out of step with the others through high ambition or extraordinary success. In either case, witchcraft ideation serves to repress jealousy and to preserve the adjustment of individuals to their social milieu. In another way, it actually institutionalises distrust. Goldschmidt (1977) found validity for this conclusion among the Kamba of Kenya, who are highly *gynophobic* men, hating and distrusting their wives with institutionalised fervour. Since it is considered bad for the man to give sexual satisfaction to his wife, the result, deriving no doubt from 'affect hunger' on both sides of the bed, is a great deal of clandestine extramarital sexual activity. The men who do not give their wives satisfaction seek and satisfy other men's wives, yet beat their own wives for being involved with other men. No wonder, they are all afraid of witchcraft from their own wives.

Much of the imputation of witchcraft is focussed on members of one's own family or immediate neighbourhood: co-wives out of envy, neighbours out of malice, and spouses out of spite, are easy targets. In fact, it is always 'the enemy within the gates', hiding behind the mask of kinship and friendship, that becomes the easiest target; it is the person with whom the ego's relationship is incorporative and not just transactional (Harwood, 1970).

(c) Externalised super-ego

Belief in witchcraft makes for externalisation of super-ego: children are sensitised to react to others. There is a double-pronged sensitisation—to those whom you trust and to those whom you do not: the former will put you to shame if you are found transgressing the social norms, while the latter will make you the victim of witchcraft. Whether it is shame about ridicule or fear of witchcraft, both these modes of functioning of the super-ego are external; there is no internal referent—no feelings of guilt or sin. Many African languages have no word for 'sin' or 'guilt'—though they have for 'right' and 'wrong', 'good' and 'bad'. "This is not due to poverty of languages, but to the fact that the concepts expressed by the European words—'sin' and 'guilt'—do not exist in African thinking" (Castle, 1967).

With the African, "An act is not sinful until it is discovered by another person; there are no secret sins in African concepts of sin. It is not sinful for a girl to sleep with a man so long as they are not discovered by someone else... sometimes, however, 'sin' will manifest itself through sickness, psychical disturbance or other form of misfortune and people begin to trace the effect to its 'cause'" (Castle, 1967). This 'cause' may be a breach of customary behaviour, and if the interests of a third party have been injured in the process, fear of witchcraft will ensue.

(d) Relieving fear of the unknown

Misfortunes, if unexplained, cause tremendous anxiety because it is not possible then to take any remedial or preventive measures. However, through oracles and divination, one can know the cause: it may be witchcraft, an evil spirit, or a displeased ancestor, once the cause has become known, suitable measures can be taken.

(e) Denial

If one has really indulged in witchcraft, one is bound to deny it, out of fear of the consequences, but even in the case of a false imputation, one may be approached by the 'victim' to remove the spell. One may not deny having indulged in the practice then, for fear that one would not be believed, but might acquiesce in doing what is requested, perhaps, entering into a blood-contract with the 'victim' that he will keep the whole affair a secret. Thus, the imputed person, may be led into believing that he is really in possession of the power of witchcraft.

Management in Psychotherapy

Witchcraft ideation is so 'other-worldly' to Western psychotherapy that little room can be found for it in the latter's conceptual framework and techniques. Unfamiliarity with the nature of witchcraft concepts, their dynamic significance, and their social function, coupled with his own inability to manage them may force a Western therapist to retreat and perhaps refer the patient to a witch-doctor (Jilek & Todd, 1974). However, this is not always in the patient's best interests: the anti-witchcraft ceremonial remedies prescribed by the witch-doctor are often exactly expensive, and in any case, referral is undesirable on moral grounds. Witch-doctors generally identify and 'name' a witch; this stigmatising fosters "labelling, mistrust, prejudice, ostracism and killing of persons who are guiltless of the crimes attributed to them" (Leighton, 1982). Also, there may well be a psychotic or neurotic condition behind the facade of witchcraft-ideation, which is outside the competence of the witchdoctor. The therapist-psychiatrist, therefore, should not shirk his responsibility, but rather enlarge his therapeutic competence to deal with witchcraft ideas, should these emerge in therapy.

Most Western therapies are essentially hide-bound within Western culture, and conditioned to specific theoretical frameworks. "More than a phenomenon, it (Western psychotherapy) is a cultural institution of this (Western) society, deriving its roots from it and, in turn, affecting and transforming the soil and era in which it thrives" (Pande, 1968). It is therefore important for a Western therapist working in non-Western cultures to be aware of the ethnocentricity of the techniques he has learnt. What is required is a pliable, strategic therapy, able to function in diverse cultural moulds. The basic requirement is a therapist who should have the ability to work with diverse world-views, keeping his own under control, and not letting it intrude unnecessarily into the patient's.

This can be called *strategic therapy*: it has often to be carried out expeditiously, but at the same time cautiously, to be launched in the hostile territory of mistrust; and must focus on the here and now of the patient's problems, with neither the time nor the inclination to resurrect presumed causation in the dead past. It has to adopt realistic goals and avoid quixotic confrontation with the culture it faces; it chooses to be 'directional' or 'non-directional', as therapeutic exigency demands. It recruits allies, e.g. the patient's family, to further its objectives. The keynote of its theoretical orientation is relevance, with responsiveness to the patient's needs and

problems—the immediate ones first. Its operational mode is flexibility—maintaining an orientation compatible with the patient's and employing techniques with which he/she is not altogether unfamiliar.

Management of mistrust

Discussing the dynamics of therapeutic relationship in its cultural perspective (Neki *et al.*, 1985a), we have observed that a patient tends to clutch at the most relevant of the 'floating transferences' in his social milieu. Thus, an African patient who believes in witchcraft tends to identify the therapist with the witchdoctor, to whom he seems to have an ambivalent attitude. "There is always a certain ambiguity regarding the status of the witch-finder, which is evident in the ambivalence with which Africans perceive them... Witchfinder and the witch share the same shadow world" (Sow, 1980) Paulme (1954) reports that the Kissi of the Guinea forest, where the witchfinder is identified with the witch, ask "how... would the witch-finder recognize witches and how would he combat them if he himself were not initiated into their secrets, if he himself were not a Kuino, a killer and eater of human flesh?" Thus, the African fears the witch-doctor as much he trusts him, and this ambivalence is easily transferred on to the therapist, who is also 'powerful and mysterious'. To this, is added the patient's distrust of hospitals in general and his lack of motivation to see a therapist. The therapist's foremost task, then, is to conquer the patient's fears and strengthen his trust. This has to be achieved rapidly, but any lack of tact undermines trust and reinforces suspicion; the therapist has to be cautious, yet natural. The patient's transference may swing to the extremes of both positive and negative, which needs deft handling.

In the West, it is customary for therapist and patient to sit in close proximity with one another—side by side, or face to face—with nothing intervening between them. However, most African patients would panic if the therapist sat next to them; it is important to let the patient sit opposite the therapist, across a table; even then, he will often draw his chair further back, to increase the distance. Careful spatial moves by the therapist, empathically monitored to patient-readiness, can bridge this distance and eventually bring about the desired proximity.

Notwithstanding the views of Sommer (1969), who considers this to be characteristic of competitive confrontation, we prefer an initial across-the-table meeting with the patient. Gardin *et al.* (1973) maintained that this arrangement increases the chances of eye-contact, and signals liking, rather

than competitive confrontation; the table provides a buffer of security to the suspicious, hostile, mistrusting or even ambivalent patient. Since there are great individual differences in patients' responses, each response should be mentally evaluated on a hypothetical scale of 'immediacy behaviour', i.e. interpersonal distance, amount of eye-contact, forward lean, and direction of shoulder orientation (Mehrabian, 1972). Exline & Fehr (1978) have experimentally confirmed that subjects reciprocate the immediate behaviour of interviewers, and further spatial dynamics must rest on mutual reciprocity.

One set of such moves are described here, as an example: although the therapist sat face-to-face with the patient, the latter, who was suspicious and distrustful, pulled his chair back and moved it to one side, to avoid direct confrontation. The therapist waited for a while before making his next move, trying to allay the patient's fears. After a short while, the patient was less ill at ease; he drew his chair closer to the table. Watching this, the therapist moved his chair sideways, so as to be face-to-face with the patient once again. As the interview continued, the patient began to lean forward on the table; then, the therapist, and following him, the patient, began to put their hands on the table. A little later, the therapist shifted his chair to bring it by the side of the table, sitting diagonally rather than in front of the patient; he thus created greater proximity with the patient, but left the corner of the table jutting in between the two of them so as not to reactivate the patient's much allayed suspicion and mistrust. As the interview further warmed up, and the therapist sensed further closeness, he chose an appropriate occasion to let reciprocal (and culturally acceptable) body contact be established, by stroking his hand over that of the patient.

In these dynamics, each step was taken after an emphatic assurance that trust had been sufficiently strengthened and fear sufficiently assuaged to make the move acceptable. The developing relationship can be injured if the steps taken are too hasty, but if, on the other hand, they are too slow, the patient—still ambivalent—might close his mind to any further therapeutic process. These moves were also performed in a natural and contextually appropriate way.

Such a step-by-step, carefully monitored spatial strategy in some way parallels Tinbergen & Tinbergen's ethological approach with autistic children (1972). In developing spatial (or 'proxemic') dynamics, interactive patterns that create effective affiliative bonding with the patient must be observed, with sensitivity at the same time to any stress caused to this bonding.

Should a patient enter therapy with negative attitudes and inappropriate expectations, the burden of responsibility to reverse these handicaps essentially lies with the therapist. The patient should be enabled to see him as an ally in this battle, which according to the patient's world-view, is against 'witchcraft' but according to the therapist's is against an 'illness'. The adversary is essentially identical, but is conceptualised in different vocabularies.

(i) Avoiding quixotic confrontation with the system

Since witchcraft ideation is a closed system, it is advisable to avoid confrontation with it: we may not accept it ourselves; but must neither decry it, nor try prematurely to educate the patient out of it. This can be frustrating, because witchcraft is a belief deeply and firmly rooted in the patient's entire cultural environment. Any attempt to dislodge it only leaves the patient confused, helpless, and more anxious. Therefore, ideological confrontation must be avoided, and though patients occasionally ask "Doctor, do you believe in witchcraft?", it is best to return a cautious answer, such as, "I am aware of this belief, held by thousands of people, but I also know that many people have suffered a great deal on account of the witchcraft they believe has been done to them. We have helped quite a number of such people". Non-confrontation means going along with the patient to the extent of 'understanding' his beliefs, but no more than that. Thus, the system can be utilised strategically, without entering it and without reinforcing it. Emphatic understanding is the best guide to avoid treading on the patient's sensitivities.

At the same time, it is important to explore the genesis and elaboration of the patient's witchcraft ideation, and to enquire what treatment he has already received or been recommended, and with what results. One should also enquire about his aetiological beliefs, and perhaps indicate one's own, though without entering into an argument. If an underlying psychotic or neurotic illness is suspected, an attempt should be made to disentangle it from the elaboration of witchcraft ideation.

The therapist may have to use active therapeutic techniques—directive, confrontative, and persuasive—for certain problems—but his approach should always be functional, never ignoring the most pressing issues of the moment. During the early phases, some medication may have to be prescribed, even if only a placebo, as well as such active intervention as assurance, advice, and environmental manipulation. The content of therapy has to be linked closely to the patient's current experience.

These strategies have, in part, also been proposed by Harper & Stone (1974), Grier & Cobbs (1968), and by Gordon (1968) in therapy with black patients in the United States.

Setting Realistic Goals

The most realistic and least controversial goal of psychotherapy, is **relief of symptoms**; this has to be achieved expeditiously, even in the first session as much as possible. It serves to strengthen the patient's trust in the therapist's 'power', and to assure him that the power of witchcraft has been stalled. Symptoms most amenable to relief need to be picked up first, and the patient given a firm assurance of relief—"I am going to take away your pain or sleeplessness, or . . . (whatever it is)". If the pain has a physical cause, an analgesic should be given; if it is due to tension, relaxation exercises. For insomnia, a (placebo) pill can be given sealed in an envelope, and the patient asked to keep it under his pillow; should he not fall asleep within half an hour, he may swallow it. Relatively few patients really need an hypnotic, which may be prescribed for a night or two to break the vicious circle. Judicious use of neuroleptics for psychosis, anti-depressants for depression, anxiolytics for acute anxiety states, and vitamins, minerals or other nutrients for deficiency disorders not only relieve major symptoms, but also serve in this way to mollify the fear of witchcraft.

Commonly associated with fear of witchcraft are conversion symptoms: aphonia, astasia-abasia, paralyses, weakness, anaesthesia, and hyperventilation are commonly seen. One of us has employed modules of single-session therapy for a medley of such symptoms (Neki, 1985b); the dramatic relief experienced appears to the patient to be nothing short of 'magical', and this convinces him of the therapist's power against presumed 'witchcraft'.

Thus, the early phases of therapy are marked by active and energetic intervention, which may consist of direct assurance, advice, or persuasion, active or placebo medication, environmental manipulation, or crisis intervention. Crisis therapy, being brief, limited in breadth and depth of exploration, and focussing on the here and now, is readily accepted. However, if the therapist seeks to alter the patient's outlook, his socio-cultural reality has to be kept in mind. "Any changes sought contrary to the dictates of belief systems surrounding him are bound to prove self-defeating" (Thomas & Sillen, 1972). Such resistance to change may, in fact, be a sign of health, and since African patients generally resist reducing their illness to a psychological level (Morakinyo,

1985), providing insight as a goal is unpragmatic and elusive. Prince (1962) found that insight therapy was not possible with Yoruba patients.

Since the patient feels so 'powerless' and bereft of strength, due to witchcraft, a second goal of psychotherapy with such patients should be helping them to gain a sense of power. To achieve this, the patient must be helped to learn to feel needed, loved, and wanted, as well as useful to himself. This can be done by assigning him carefully graduated useful tasks, which can be easily carried out; doing them engenders feelings of satisfaction, and relieves the patient of his negative self-image, as well as his non-commitment.

It is advisable to focus on pragmatic life strategies, and persuade the patient to try them out. Patients soon realise then that they have more control of their destiny; they have generally been unaware of the many options of action open to them, but making them aware of these, and helping them to exercise a suitable choice enables self-confidence to be regained.

Appropriating the functional dynamics of the witchcraft system

Whilst witchcraft should be neither confronted nor strengthened the functional dynamics of this system can be appropriated into psychotherapy. The witch-doctor 'understands'; he has no need to enquire, but informs. So our enquiries must be kept to the minimum, at least in the beginning, but through empathic understanding, the therapist tries to know what is happening to the patient, and to make him feel understood. What the patient may have only haltingly and inadequately expressed may be reformulated in clearer terms: 'mirroring' back to him his own thoughts, formulated more clearly, makes him feel understood. Thus, the therapist tries to make the patient feel understood, and clinical experience enables him to guess more than he has been told; communicating what one has thus guessed back to the patient is also reassuring.

Relevance, which is always the key note, has to be also in the patient's eyes, and not just in those of the therapist. Hence, detailed enquiry, especially about the patient's past, which is not seen by him to be immediately pertinent, is avoided. Later on in therapy, it is generally possible to delve into the requisite details of patients' lives.

The language employed by the therapist should be syntactical to that of the patient; this term is used in a broader sense than usual, and includes concepts, myths, ideas, etc. In other words, the 'idiom' of the therapist should be congruent with that of the patient. For instance, a patient said, "Doctor, I

know a baby doctor, a bone doctor, but I never know psychia—what do you call it?. Yeah, psychiatrist. What kind of doctor are you?". The psychiatrist, who knew that the patient's culture is characterised by physical expression and human relationship rather than abstract thinking and intellectual discussion, answered, "I am a heart doctor. I help people with worry in the heart". The patient was then sure that she was seeing the 'right kind of doctor' for, as she explained, "my heart has lots of worry" (Tseng & McDermot, 1981). A useful form of explanation is—"I am a doctor who helps patients get rid of their . . . (here mention is made of the main symptom(s) of the patient), whether or not caused by witchcraft". All along, it is important to be open and direct, and to provide unequivocal feedback to the patient about what the therapist understands of his problems, and the instructions he wants to give him.

Since a witch-doctor generally prescribes ritualistic remedies, the patient in therapy also expects to be involved in a ritual of some kind. Most cultures have their own remedial rituals—of handling grief, separation from the dead, restoring harmony with family or group, or combating fears—natural and supernatural. The patient may be encouraged to make use of these as a parallel to psychotherapy, without supplanting it, and some ritualistic activities may be incorporated into therapy. One of us (BJ) employs relaxation therapy for this purpose, while role-playing and modelling may also be utilised; these not only employ a physical, action-orientated style, but also stimulate introspection. Patients may even be given 'home-tasks'; one of us (JSN) asks his patients to record or remember their dreams, and to bring them to subsequent therapeutic sessions. Apart from the 'window' they provide into the patient's dynamics, dreams also have an esoteric meaning, so that the therapist who makes use of them makes the patient feel doubly assured of his prowess. The content of dreams can be used to lift a patient's morale; one had felt that he had been bewitched since he dreamt of having eaten at the hands of a stranger. Later, he had another dream, in which he found his house being cleaned and white-washed; this was interpreted to counter the significance of the first.

Recruiting allies

The patient's family can be great allies in therapy. Whether they have to be involved directly (family therapy), in the patient's 'home-work', to supervise his compliance, or just be kept in touch regarding progress is a decision which has to be taken in each

individual case. Family therapy, for example, was dictated by the needs of the following case:

A 25 year-old girl, suffering from pulmonary tuberculosis, came to the hospital, and the physician had her chest X-rayed; when she went to collect her report, the film could not be found. The same happened with repeat X-rays, taken twice more. She then gave up the chase, saying, "I know these X-rays are not going to be found. I have been bewitched, that is why!". On further enquiry, she averred having married a man against the wishes of her family; she had in fact become pregnant by him, even before marriage, and her grandmother had never been reconciled to this. The patient now felt that it was the grandmother who had bewitched her. Family therapy, involving the grandmother herself, led to the resolution of the conflicts and tensions.

In rallying allies for the patient, one has to scan his social network, and identify who can be the best source of support—father, mother, a particular sibling, employer, friend, priest, or traditional healer. Home visits provide a good avenue for studying the family dynamics.

For the sake of his patient, the therapist may have to plead with housing authorities, welfare agencies, employers, schools or courts of law. The witch-doctor has his extensions into the community, and if the therapist also has such contacts, his effectiveness becomes greater.

Studying the dynamics

The therapist studies the patients dynamics not with the objective of providing interpretations or insight, but to inform himself so as to be able to help the patient more effectively. To start with, the therapist must evaluate the patient's attitudinal dynamics: is he of a mistrusting or a dependent kind? Is he approaching therapy with interest, doubt, or

apathy? The findings will determine what strategy the therapist must adopt.

It is also important to find out what sort of feelings lurk behind the expressed fear of witchcraft. Is it aggression, fear of punishment due to moral transgression, jealousy or fear of presumed jealousy, the desire to escape responsibility for personal failure, or the irksomeness of some relationship? Different feelings warrant different management strategies. There is a need to identify defensive denial of inner feelings of weakness, fear of being discovered, reliance on maintaining a false image, or malingering. All these require handling in a way that does not cause loss of face to the patient.

Reality factors often intrude into psychotherapy: conflict, jealousy, frustration, suspiciousness, or confusion may easily arise if the patient's aspirations collide with reality, and all can rekindle witchcraft ideation. The patient must be helped to appreciate alternative possibilities, and to fortify his adaptive skills; he may also have to be helped to 'accept' the world, in existential terms.

The therapist is often faced with the dilemma of whether to lay emphasis on autonomy and self-actualisation, or on group solidarity and conformity. It is essential then to find out the sheet-anchor of the patient's personal values and to provide him with the means of making restitution toward that system of values. Empathy must not be with the patient alone, but also with his culture, and cultural empathy cannot be gained merely from academic information about any group. This has to be done by sharing actual life-experiences with people—visiting their homes, joining them in their ceremonies, breaking bread with them, and observing them in both formal and informal social occasions. It is only through such cultural empathy that proper understanding of culturally rooted problems can arise.

Behaviour Problems in Retarded Children with Special Reference to Down's Syndrome

ANN GATH and DIANNE GUMLEY

Data were collected, using interviews with parents and teachers and rating scales, concerning the behaviour of two groups of mentally retarded children: 193 children with Down's Syndrome (DS) and 154 children with a similar degree of handicap were identified in the same schools. The proportions of children who had high scores on the Rutter or an additional behaviour check list, were similar in the two groups. Deviant behaviour was markedly more common in both sets of retarded children than in their siblings next in age; 31% of the children with DS and 29% of controls were judged to be well adjusted, while 38% of the DS children and 49% of the controls had significant behaviour disorder. Conduct disorders were most common in the children with DS. 'Psychosis' was the most common diagnostic label in the control group, but was also found in the children with DS.

Behaviour problems are a common and distressing complication of mental retardation: indeed it has been argued (Webster, 1970) that psychiatric disorder is an almost inevitable accompaniment: he could find no child who was 'simply' retarded in a group of Boston children aged 3-6 years. Webster described the "primary psychopathology" of retardation, the characteristics of which were "repetitiveness, inflexibility and simplicity of emotional life". However, Chess & Hassibi (1970) in their study of 52 children living at home, aged between five and twelve years and with mental ages of between four and six years found that 40% showed behaviour that could be accounted for by the fact of retardation alone, without psychiatric disorder. The features described by Webster as signs of 'primary psychopathology' were considered by Chess (1977) to indicate merely lack of ideas, which is an integral part of mental retardation.

A very high rate of psychiatric disorder in retarded children was noted by Philips & Williams (1975) who found only 13% free of it among clinic attenders, but there was likely to be a referral bias in this group towards children with problems. In another clinic for retarded children, 24% were considered to have a primary emotional disorder and 30% emotional problems secondary to other developmental difficulties (Szymanski, 1980). Kamimer *et al* (1984) found a 75% rate of behavioural or emotional problems among 167 children evaluated at a clinic: their criteria for 'no problems' were that the child was compliant to adult requests, interacted with appropriate affect, had no deviant behaviours

noted or reported, and showed a level of attentiveness and activity appropriate for his mental age level, and that the parent did not report management problems. These are stiff criteria, and the findings were not validated by comparison with a control group of children in the normal range of intelligence, judged by the same yardsticks.

The evidence from epidemiological studies indicates that psychiatric disorder becomes more common with decreasing levels of intellectual functioning (Rutter, 1971; Corbett, 1977). Rutter *et al* (1970) had defined psychiatric disorder as a disturbance of behaviour or emotions sufficiently severe and prolonged to cause suffering to the child, to the family, or to the community. By this definition, the incidence of behaviour disorders in severely retarded children in the Isle of Wight study was 50%, compared with 6.6% among in the normal range of intelligence. This figure for retarded children is similar to those found in retarded children in Scotland (Birch *et al*, 1970; Koller *et al*, 1983) and in Camberwell (Corbett, 1977), but somewhat lower figures were reported by Stein & Susser (1975) in severely retarded children aged 5 to 14, 20% of whom had behaviour problems, and by Groden *et al* (1982), who found 25% out of 1114 retarded children in Rhode Island had behavioural and/or emotional problems.

Some investigators have attempted to determine what sort of disorders are seen in retarded children: 38 of the 100 children described by Philips & Williams (1975) were classified as psychotic, while, of the rest, 26 had behaviour disorders, five had

neuroses, two had transient situational disorders and 16 personality disorders. The making of specific psychiatric diagnoses is particularly difficult in retarded children, but the recent trend to multi-axial classification in I.C.D.9 (World Health Organisation, 1978) and D.S.M.III (American Psychiatric Association, 1980) seems to have made the task a little less daunting. 'Psychosis specific to childhood' was the most common diagnosis made in the Camberwell survey (Corbett, 1977), being found in 17% of children, with 6% showing adjustment reactions and emotional disorders; conduct disorders and hyperkinetic syndrome were each found in 4% of his sample while a relatively large group, 12%, had to be classified under 'Special symptoms or syndromes not elsewhere classified'. Reid (1980), found conduct disorders to be most common, being diagnosed in 27 out of 60 clinic attenders. Of the remaining 33 children, 13 showed neurotic disorders, four had adjustment reactions, nine had the hyperkinetic syndrome, five had childhood psychosis, and one was manic-depressive leaving one girl unclassified.

There are references in the literature to subjects with Down's syndrome (DS) being less prone than other retarded people to the severe complications of mental retardation of which behaviour disorder is one (Kushlick, 1975). The personality stereotype of someone with DS is adaptable, humorous, and affectionate, with skills in mimicry (Smith & Berg, 1976), and recent studies appear to confirm that DS children are easy to manage (Gibbs & Thorpe, 1983; Gunn & Berry, 1985). In a review of the personality characteristics associated with DS, Gibson (1978) concluded that age, IQ, and ability to communicate are important whereas older children, particularly post-pubertal boys, are more likely to show aggression, hostility, or sullenness. However, in a longitudinal study, Carr & Hewett (1982) noted that 22% of the mothers of 11-year-old children with DS said they had worries about their children's behaviour, but that five years later, three quarters of the children were described as 'easy' and the rest as 'fairly easy'.

There are conflicting reports of the incidence of psychiatric disorder in DS children. Webster (1970) considered such children to have only minor degrees of emotional disorder, but on the other hand, Menolascino (1970), found 37% of a sample of 54 boys and 41 girls with an average age of 13.2 years to have a psychiatric disorder. The present authors followed a small group of children first seen in infancy (Gath & Gumley, 1984) and found that eight out of 14 boys and three out of eight girls had behaviour problems, as shown by deviant scores on standardised behavioural rating scales, but that nine

controls (normal children born at the same time to similar families) also had deviant scores on the same scales.

Method

Children with DS were identified, using the School Health Service records, in one Health Region in England. Each was matched, in the same school, with another child of the same sex and age and with a degree of physical and mental handicap as close as possible to the index child. The general practitioner was contacted before any approach was made to the parents of any child. Data were collected during the period 1979-1982: a member of the research team carried out semi-structured interviews with the parents in their homes. The parents were asked to complete the Rutter behavioural scale A2 for the identified child and for the sibling next in age who was also attending school; they also completed Part 1 of the Adaptive Behaviour Scale (Nihira *et al.*, 1974) and an Additional Behaviour checklist, consisting of items of behaviour found to concern parents of children with DS in a previous study (Gath & Gumley, 1984). With the permission of the parents, the clinical psychologist visited the school attended by the Child with DS and interviewed the teacher; the control child was selected at this meeting. Teachers completed the Rutter B2 scale, the Adaptive Behaviour Scale, and the Additional Behaviour checklist for both the children.

Results

Subjects

One hundred and ninety three children with DS, 94 boys and 99 girls, were enrolled: ages ranged from six to 17 years. The control group consisted of 154 children, 76 boys and 78 girls, attending the same schools and with a similar degree of verbal and motor handicap: 87% of the children with DS and 89% of the controls lived at home with at least one natural parent while seven children with DS and four controls were in long-stay hospitals. General practitioners had refused consent to the participation of one family with a DS child and of four families of the control group; 18 families with DS children and 16 families in the control group had refused to take part in the study. The refusal rates were thus 8.96% for the DS group and 11.5% for the control group, and 90% of the families approached in fact took part in the study.

Teachers completed the Rutter B2 rating scale and the Additional Behaviour checklist for 170 of the DS children and for 136 of the controls—a response rate of 88% for both groups.

Adaptive Behaviour Scale Scores: The range of raw scores on the Adaptive Behaviour scales were similar in the two groups (Figures 1 and 2). The means for each age group were similar in the Down's syndrome group and the controls.

FIG 1 AAMD Adaptive Behaviour Raw Scores.

FIG 2. AAMD Adaptive Behaviour Raw Scores.

TABLE I
Down's syndrome children and similarly handicapped controls: deviant scores on Rutter behavioural rating scales

Scale used	DS children	Controls
	<i>n</i> = 193	<i>n</i> = 154
Rutter A2 scale		
(score 13 or more)	66 (34%)	63 (41%)
mean	11.23	12.84
	$(\chi^2 = 1.045, d.f. = 1 \text{ NS})$	
Rutter B2 scale	<i>n</i> = 170	<i>n</i> = 136
(score 9 or more)	53 (31%)	58 (42.6%)
mean	7.55	9.2
	$(\chi^2 = 3.8184, d.f. = 1, P < 0.05)$	

Rutter Behavioural Rating Scales: There were no significant differences in the percentages of children who had deviant scores, defined as 13 or more on the Rutter A2 scale, completed by the parents. The control children, however, were more frequently found to have deviant scores of nine or more on the Rutter B2 scale as completed by teachers (Table I). Parents reported more neurotic symptoms in the control than in the DS group. Both parents and teachers found significantly more hyperactive behaviour in the control than in the DS children. Anti-social sub-scores were similar in the two groups.

Additional Behaviour Checklists: Seventy three (38%) of DS children and seventy one (46%) of controls had scores

of ten or more on the Additional Behaviour checklists as completed by parents and 30% of both groups as completed by teachers. Individual items of behaviour on the checklists also showed few differences between the groups. The most frequent item reported was that the child became very distressed if corrected, which appeared to inhibit the parents from disciplining him or her. Aggressive gestures, rebellious behaviour, attention-seeking and interference with the persons or property of others were common in both groups; the least common behaviours were head banging, inappropriate use of the toilet (e.g. by drinking from it or stuffing it with paper), and fire setting. Behaviour associated with psychotic disorders in childhood, such as stereotypies, use of objects as twiddles or unresponsiveness were as frequently found among DS children as among the controls. Running away was reported in one in four of DS children (24.5%), but in only one in eight (12.5%) of the controls ($\chi^2 = 3.999, d.f. = 1, P < 0.05$). Shouting or screaming was reported in 33.5% of the controls, but in 19.4% of the DS children ($\chi^2 = 4.427, d.f. = 1, P < 0.05$).

Comparison with siblings next in age Ninety nine children, 56 boys and 43 girls, with DS and 92, 50 boys and 42 girls, among the controls had a sibling who was still attending school and within five years' age difference. In the DS families, there were 51 sisters and 48 brothers, and in the control families 32 sisters and 60 brothers who fulfilled the criteria. In the DS group, 58 were older and 39 were younger than the retarded child, while in the control group, 40 were older and 49 were younger. There were two sets of twins in the DS group and three sets in the control group. (None of the twin siblings were retarded.)

A2 behavioural rating scales were completed by the same parent for each paired retarded child and sibling: deviant scores were found in 30 DS children and 11 siblings ($\chi^2 = 9.996, d.f. = 1, P < 0.01$) and in 33 controls and 11 siblings ($\chi^2 = 13.17, d.f. = 1, P < 0.001$).

High neurotic, anti-social, and hyperactive sub-scores were each found in between 3 to 5% of the siblings—much less frequently than in the retarded children.

Children with no behaviour problems: Fifty nine children with DS (31%) and 46 controls (29%) had no deviant scores on either scales or on the Additional Behaviour checklists. These children had no more behaviour or emotional problems than children in the average range of intelligence and could certainly be regarded as normal or well adjusted.

Children showing severe behaviour problems: Seventy four (38.3%) of the 193 children in the DS group had high scores on at least one of the Rutter scales with a score of ten or more on the Additional Behaviour checklist, as rated either by parents at home or teachers at school, or by both. In the 154 controls, 74 (49%) also had significant behaviour problems or were definitely deviant by the same definition. Serious behaviour problems were more

Down's syndrome children v. Handicapped controls

Boys	$\chi^2 = 0.314$, d.f. = 2	NS	
Girls	$\chi^2 = 5.819$, d.f. = 2	$P < 0.1$	NS
Both sexes	$\chi^2 = 4.474$, d.f. = 2	NS	

common in the children with low scores on the adaptive behaviour scales. There were 17 children in the DS group with adaptive behaviour scale scores of below 100 both at home and at school—well below the mean for any age-group; 14 (82%) had severe behaviour disorders and the other three were in the borderline group ($\chi^2 = 20.54$ d.f. = 4, $P < 0.001$). Eleven children with DS had very low adaptive behaviour scores in one situation only, either at home or at school, and seven of these also had severe behaviour disorders which tended to be situational—associated with low expectations or achievement.

Similarly, 11 (78%) of the controls with very low adaptive behaviour scale scores had severe behaviour disorders, as did all 7 children with low adaptive behaviour scale scores in one situation only ($\chi^2 = 15$, d.f. = 4, $P < 0.001$). Behaviour disorders tended to be less common in the most competent children in both groups.

Possible behaviour disorders: Sixty children with DS and 34 in the control group were regarded as on the behavioural borderline (Tables II and III). The difference between the two groups fell just short of significance at the 5% level ($\chi^2 = 5.7569$). More girls in the control group were deviant than in the DS group, the difference being very close to significance ($\chi^2 = 5.819$ d.f. = 2). Similar proportions of boys in the two groups had many behaviour problems.

Psychiatric Diagnoses: The majority of the children with severe behaviour problems could be classified, using Axis I of ICD 9, as shown in Table IV. DSM-III diagnoses agreed with those under ICD 9 except for 299.8 under ICD 9 'Psychosis with origin specific to childhood' where the DSM-III diagnosis of Pervasive Developmental Disorder was considered more appropriate but for its stipulation that the disorder had to have developed before the age of 30 months. Multiple diagnoses are possible on the DSM-III system so that, for example, hyperactivity and conduct disorder were both coded.

Two children with DS and three of the controls fitted the criteria for infantile autism. More boys than girls in both groups were diagnosed as having a 'psychotic' disorder, including autism, but this difference is not significant with the small numbers concerned. More girls than boys in the handicapped control group were judged as having an unsocialised conduct disorder, corresponding to 'unsocialised aggressive disorder' in D.S.M. III., in contrast to the DS group, where this diagnosis tended to be

TABLE IV

more common in boys. Hyperactive conduct disorder was a diagnosis which tended to be more commonly made in the DS group, but there were somewhat more controls who did not fit into any diagnostic category. Conduct disorders and psychoses were found in all age-groups, in both DS children and the controls, but hyperkinetic disorders tended to be found more, though not exclusively, in the younger children. Psychoses were found in the more able children with higher adaptive behaviour scores but were

more numerous in the children with lower adaptive behaviour scores.

Discussion

The results of this study reveal that a significant proportion of children show problem behaviour, which causes suffering to them and to their families. In this, they are little different from a group of children, whose retardation arises from many other causes.

When a measure standardised for use with children within the normal range of intelligence is used, many more of the children with DS have scores that are judged as deviant than do their siblings closest in age. The DS children are, in this respect, as different from their siblings as the controls are from their brothers and sisters. The two groups of retarded children also show a number of behaviour and emotional problems in addition to those rated on the Rutter scales. A similar proportion (30%) of children in the two groups of retarded children, had no behavioural or emotional problems on any of the measures used in our study. This finding is less, though not significantly so, than that of Chess & Hassibi, but is certainly larger than that found in most of the studies of clinic populations. The proportion of children with definite disorder is less than that found in most epidemiological studies of mixed groups of retarded children. However, in this study, a borderline group is included, since no evidence could be found for a clear cut off point between normal, well adjusted children and those with behavioural or emotional disorders. A continuum of deviancy is a more accurate concept than one of health and disease. Behavioural problems are much more common in those children who have been unable to learn appropriate behaviour, as measured by the adaptive behaviour scales, on which scores were found to be related to measured intelligence quotients in a group of children with DS who had been followed from infancy. It is therefore likely that severity of intellectual handicap is an important factor in the development of the disorders.

As in most other studies, the most common diagnostic group in our controls was that of psychosis (17.5% including autism)—very similar to the proportion found in Camberwell but less than in most clinic samples. The proportion of DS children with severe psychiatric morbidity was not markedly different at 9%, certainly higher than might be anticipated from most of the literature on DS. However, this label of 'psychosis' is unsatisfactory, not reflecting the flavour of the problems the children showed; Tanguay (1984) discussed the diagnosis of severe

psychopathology in children in a developmental context. The next revision of the two systems of disease classification may contain categories with less pejorative and more accurate labels. Conduct disorders form the most common diagnostic group for children with DS (11%) and are almost as frequently found in the controls (10%). Hyperkinetic conduct disorder was more often found in the DS group (which appears to contradict the finding that hyperactive behaviour was significantly more often found in the controls). The psychotic children, often with histories of brain damage, in the control group had very high hyperactive scores.

Ineichen (1984) has questioned the findings of some studies on the prevalence of what has been termed 'mental illness' in retarded patients, particularly in hospitals. It is suggested that some at least of such 'illness' may be attributed to the poor environment or to failure to teach appropriate skills. Only a very small proportion of the children in our study were living in institutions; most of the children enjoyed family life as did their siblings. However, many of their disorders, particularly those grouped

rather unhappily as 'psychosis with origin specific to childhood: other', did appear to be related to the failure to communicate and to learn more acceptable ways of attracting attention or even passing time. Psychiatrists themselves have suggested that many children who are retarded do not need the attention of psychiatrists (Tarjan, 1977; Wortis, 1977), and these would include nearly one-third of all the subjects in this study. Nevertheless, a sizeable proportion of retarded children, just under 40% of those with DS but nearly half of the mixed group of similarly retarded controls, do have severe and distressing problems that require a broad range of psychiatric skills and understanding in order to make a valid diagnosis.

Behavioural and emotional problems are a serious secondary handicap for between four and five out of ten children with mental retardation and children with DS have nearly as many problems of this sort as other children similarly handicapped. There is, however, clearly a role, though not an exclusive one, for the psychiatrist in investigating and treating the problems described.

British Journal of Psychiatry (1986), **149**, 161-171

Family Background of Children with Down's Syndrome and of Children with a Similar Degree of Mental Retardation

ANN GATH and DIANNE GUMLEY

The families of Down's Syndrome children and another group with a similar degree of retardation were compared using data collected at interview. Differences in social class distribution were explained by the maternal age effect in the Down's group. Divorce was more common in the control group but the quality of marriage in those parents still together and the health of parents were similar. No close associations were found between behaviour disorders in the children and family factors, except that behaviour disorders were likely to be associated with similar disturbance in siblings next in age and to be more common in the less happy marriages.

The literature concerning families of mentally retarded children is mostly concerned with the effect upon parents and siblings of the additional burden that bringing up a handicapped child imposes. Evidence from earlier studies was used to support the case for long-term hospital care; even families who

wanted to bring up the retarded child at home often felt themselves driven to request such care for their children because they could not cope with the demands upon them, (Oster & van den Tempel, 1975). The emphasis thereafter moved strongly to "community" care, and with more positive attitudes

to retarded children, including provision of education for all children, and some social support such as occasional relief care, more encouraging findings from research on families has appeared. One long-term study (Carr & Hewett, 1982) followed infants with Down's Syndrome (DS), originally investigated by Cowie (1970), to the age of 16, and found that a number of families were coping well and enjoying a good life in many ways. Similar positive findings were also noted in the follow-up of another group of children with DS first seen in infancy (Gath & Gumley, 1984).

There are, however, indications that some adverse effects on families occur quite early on, before the care of the child itself becomes very different from that of a normal child (Gath, 1977, 1978). These early effects are concerned with the 'value crisis' (Wolfensberger, 1968) which follows the initial shock, and occurs when the parents are forced to revalue many of their previous beliefs. Some marriages did not survive this revaluation, and others continued with deep rifts. Later effects, such as increased psychiatric morbidity in parents, shown when the children were aged eight or nine, are more related to what Wolfensberger called the 'reality crisis' and Tizard & Grad (1961) the 'burden of care'.

Recent research on families of mentally retarded children has moved from the negative approach of measuring what was assumed to be the inevitable stress upon other family members to looking at positive and negative effects in both directions. Strengths as well as weaknesses of parents and siblings are noted, particularly in relation to their ability to cope with not only the added work of caring for a more dependent child, but also the considerable demands of treatment. Objective measures of the way families actually live with a retarded child have now been developed. Bringing up such a child is extremely hard work, especially for the mother (Dupont, 1980; Wilkin, 1981; Pahl & Quine, 1984). Parents are now expected to take an active part in early education as well as in any physiotherapy or behavioural therapy which may be prescribed for the common additional problems. Even when these secondary handicaps become very severe, it is no longer common practice to admit the child for intensive therapy away from the family as the improvement often fails to generalise on discharge. Instead, the other family members are enrolled as co-therapists from the start and must learn and then continue the treatment programmes devised by professionals.

Our previous paper (Gath & Gumley, 1985), describes the behaviour problems in two groups of

retarded children, one with DS, which makes up the single biggest diagnostic group in special schools, and the other of children chosen by the teachers as having comparable verbal and physical abilities. Behaviour disorders were common in both groups, but slightly less so in the DS group. The present paper aims to compare the socio-demographic backgrounds of the two groups, and to look for factors particularly concerned with the presence of behaviour disorders in retarded children.

Method

Children with DS were identified in schools in one Health region and were matched where possible with a similarly retarded child in the same class. The parents were interviewed in their homes using a semi-structured interview which was recorded on tape and coded by an independent rater. Part of the interview consisted of an assessment of the quality of the parents' marriage based on that devised by Brown & Rutter (1966) and used in previous studies of the families of retarded children (Gath, 1977, Gath & Gumley, 1984). A judgement was made of the quality of the marriage, particularly of the warmth and/or hostility evident throughout the interview. A further judgement was made of the state of mental health in both parents; this was based on the General Health Questionnaire (Goldberg, 1972) and on answers to questions concerning symptoms in the interview. Degree of incapacity was determined from the ability to work or to cope with home chores and the impression from the interview as a whole. This second judgement was agreed upon by the interviewer, the rater, and the first investigator.

Specific questions were asked about the sibling closest in age to the retarded child. Parents completed the Rutter A behavioural rating scale and, with their permission, teachers completed the Rutter B behavioural rating scale and a school report form.

As described by Gath & Gumley (1986), all the retarded children had been assessed on the American Association for Mental Deficiency Adaptive Behaviour scale (Nihira *et al.*, 1974). They had been divided into three groups—those with definite serious behaviour disorders, those with no behaviour disorder and a borderline group.

Results

Family interviews had been carried out in the homes of 192 of the children with DS and 147 of the children with a similar degree of mental retardation.

Age. The mean age of the children with DS was 11.77 years with a range of 6–17. The mean age of the control children was 11.82 years

Home and parents: One hundred and sixty-three (85%) of the children with DS lived at home with both natural parents. Thirty-one children with DS and 12 controls were

not living full-time with at least one natural parent. Three DS children were in boarding schools out of the region, but returned home for holidays and half terms. All the other children went to schools in the region, as did all the controls. Ten DS children and 3 controls were in the hostels run by the local authority, but usually went home for holidays and often for weekends as well. Comparable children were found as controls for four of the seven children with DS who were in long-stay hospitals for mentally handicapped patients. No suitable matches could be found for those in boarding schools. Three children with DS were adopted, as were two of the control children. Four families had made the adoption in the full knowledge of the child's retardation and associated medical diagnosis. The exception was one couple whose originally normal baby, adopted at three weeks, had suffered severe brain damage following encephalitis at the age of four. Eight DS children and 3 controls were in long-term foster care.

Parents' understanding of the handicap: Since DS is apparent from birth, there were marked differences between the two groups of parents as to when they first understood that their child had a handicap: 42% of the parents of the DS children said they knew immediately after the birth, and a further 30% said they knew during in the first week, compared with only 9% of the parents of the controls who had learnt by the end of the first week. Only 3% of the DS group felt they had not clearly understood about the handicap until after the first birthday, while 41% of the parents of the controls had learnt about it between the first and fifth birthdays, and in 9% of cases, the child had already reached compulsory school age before they knew.

All the parents of the DS group knew that their child had the syndrome or 'was a Mongol'. In 13 of the controls, there was no information about the parents' understanding of the child's handicap. Fifty (34%) thought the child had brain damage, 13 (9%) mentioned a specific syndrome, e.g. San Filippo disease, 53 (36%) had been told that there was no medical disorder but that their child was 'just generally backward' and 18 (12%) believed there was an underlying medical condition, as yet undiagnosed.

Ethnic origin: The majority (180, 93%) of the children with DS were Caucasian, with parents and grandparents born in the British Isles. Four were children of Caucasians from other European countries, five were children of Asian immigrants and five had parents born in the West Indies. The ethnic background of the control group was very similar, with four from other European countries, three from Asia and one from the West Indies.

Family size: The families in the Down's were larger than those in the control group, but the difference was not great. The mean sibship size in the Down's families was 3.44, with a range from one to ten, while that of the other families was 2.9, with a range of one to eight. Mean sibship size dropped from 4.0 in the families of the 16 year old children to 3.07 in families of the children aged 6-8 in the DS

group, but remained much the same in each age-group in the families of the controls. Fourteen DS children and 11 of the controls were only children, i.e. 11% of both groups.

Slightly fewer, 37 (22%) of the DS group, were first-born, compared with 53 (39%) of the control children. The mean ordinal position of the retarded child was 2.9 in the Down's group and 2.3 in the controls. Just over half the children with DS were the last born in the families, excluding only children, as were 63 or 46% of the controls.

Social class: There was a shift towards social classes I and II in the Down's as compared with the control group, ($\chi^2 = 7.257$, d.f. = 2 $P < 0.05$). The social class difference was insignificant in the children aged 12 or more, but was most marked in the youngest group, aged between six and eight at the time of assessment. The social class of 14 families in the DS group and of five families in the control group was not ascertained, as the fathers were either long dead or divorced, and their job status was unknown. Family size was related to social class in the control group only (Table I). Large families were common in all social classes in the DS group. There was a marked social class difference related to the parents' understanding of the nature of the child's developmental difficulties, with over-representation of social classes IV and V in the group who believed that there was no medical explanation for their child's retardation. The social class distribution of the DS group more closely resembled that of the families of the brain-damaged children or of those with specific syndromes.

Maternal age: Mothers of the children with DS were older at the time of the birth than were those of the controls, the mean ages at the time of the birth being 33.53 and 28.03. The age gap was greatest in the small group where the social class of the father was unknown. As expected, mothers who had been aged 40 or more at the birth of the retarded child were much more common in the DS group, numbering 58 (28%) as against only seven (5%) in the control group ($\chi^2 = 29.3$ d.f. = 1, $P < 0.001$). By contrast, there were 13 (9%) young mothers aged 20 or less at the birth of the child in the control group, and six (3%) in the Down's group, ($\chi^2 = 4.14$, d.f. = 1, $P < 0.05$). The mean age of mothers and the total family size tended to be less in the younger groups of children. Mothers of DS children were more likely to have done well at school and to have had further education: 26 mothers of DS children had had professional training, particularly as nurses or teachers, and ten had a university degree, compared with ten and two respectively of the control mothers, ($\chi^2 = 15.37$, d.f. = 3, $P < 0.001$).

Marital relationship of the parents: The natural parents were no longer together in 32 families in the DS group and in 35 families in the control group. There were nine widows and one widower in the Down's group and six widows in the control group. Twenty-three marriages were broken by divorce in the control group, but only ten in the DS group,

$(\chi^2 = 7.3, \text{d.f.} = 1, P < 0.05)$. There was no significant difference between the quality of the marital relationship in those families where the natural parents were still living together. In four of the DS group and one of the controls, no information was available on the natural parents. Good marriages were evenly distributed throughout the social classes in both groups, but very poor marriages tended to be more frequently found in social classes IV and V.

The health of the parents: The physical health of the mothers was considered to be a problem in 17% of the families of DS children and 13% of the families of controls. A similar degree of concern about the fathers' health was expressed by 15% of families of DS children and by 12% of controls. Many mothers described themselves as suffering from 'nerves', but there were slightly more of these in the control group—42% as opposed to 39%. Fathers were less commonly affected by 'nerves'—22% of the control group and 14% of the Down's group. Scores of ten or more on the General Health Questionnaire were obtained from seven mothers and two fathers in the Down's group and six mothers and seven fathers in the control group.

Severe mental illness (incapacitating, necessitating admission to a psychiatric hospital and/or inability to cope for at least a month in the past year) affected 2.8% of the whole group of parents and was evenly distributed among mothers and fathers in both groups. There was one case of manic-depressive psychosis in the DS group and one case of schizophrenia in the control group. The remainder of the affected parents suffered from depression (Table II). Minor disorder, causing distress and some impairment of

the capacity to cope, was found in twice as many mothers as fathers in both groups. There were few differences between the groups, but despite more mothers of the controls reporting problems with 'nerves', a clinical psychiatric disorder was judged to be present slightly more often in the mothers of the DS group. A mixture of anxiety and depressive symptoms was reported in most cases. In all, 46 mothers and 20 fathers in the DS families were judged as

TABLE III
Psychiatric disorder in parents and quality of parents' marriage

having a psychiatric disorder. In 12 families, both parents were affected; 33 mothers and 21 fathers in the control group had a psychiatric disorder, with both parents affected in eight families. Psychiatric disorder in the parents of both groups of children was closely correlated with the quality of the parents' marriage (Table III).

At least one parent, but in many cases both, had a psychiatric disorder in ten of the eleven most disharmonious marriages in the Down's group and in all the very poor marriages in the control group. Widowed and divorced mothers, by contrast, were not particularly vulnerable in this respect. Psychiatric disorder showed a gradual increase with social class. In class I, 19% of the children with DS and 20% of the controls had a parent with psychiatric disorder. The percentages of affected families in social classes IV and V rose to 30% for DS and 35% for the controls. Psychiatric disorders was not more common in older mothers.

Brothers and sisters There were 99 siblings in the DS families and 92 in the families of the control children who were still at school and aged within five years of the retarded child. Eleven (11%) of the siblings of the DS children were regarded by their parents as having significant problems and 12 (13%) of the control siblings. The ratings made by the parents were very similar to those on the Rutter A scale where five boys and six girls in the DS group and seven boys and four girls in the control families had high scores. More siblings, 15 boys and eight girls, in the families of the controls had high scores on the Rutter B behavioural scale, as rated by the teachers, compared with nine brothers and eight sisters of the DS children. There were no significant differences between brothers and sisters or older or younger siblings in either group. Behaviour disorder in the siblings was closely related to that of the retarded children in the families of DS children but not in the families of the controls, (Table IV)

Practical aspects of family life: Very few families employed paid help. The eight who did have paid help all came from the DS group; five were from social class I and three from class II. More families in the control group depended upon a grandmother of the child for help: 35 (24%) of the controls and 27 (14.5%) of DS children had grandmothers who were a regular and important source of help ($\chi^2 = 4.087$ d.f. = 1, $P < 0.05$). Sixty-one (33%) of the families of the DS children were helped regularly by a neighbour or friend, compared with 33 (22%) of the families of the controls ($\chi^2 = 3.84$, d.f. = 1 $P < 0.05$).

Slightly fewer in the control group of families (48%) had regular annual holidays than did the families in the

DS group (58%). Similar numbers went on family trips altogether or the parents went out as a couple. Only 8% of each group felt they had major problems making baby-sitting arrangements.

Support services: During the pre-school years, the family doctor and health visitor provided most support, and despite the more regular contact of the health visitor, parents were more appreciative of the help offered by the doctor. A significant minority, 29%, in both groups, could name no reliable source of help or advice when their children were small. Once the child had gone to school, more (21%) of the parents in the DS group still felt they had no one to turn to, compared with 12% of the control parents. The doctor's involvement did not lessen although in 15% of cases the school staff were rated as equally important. The teachers were consulted about problems almost as frequently as doctors, and a fifth of the parents regarded them as the main source of help with the retarded child. Social workers were seen as closely involved in less than 3% of all the families.

The majority of parents, more than 80% in each group, felt that the school concerned was the right one for their child's particular needs. Relief care was available for the families. 44% of both groups of families used hostels, of which there was at least one in each county. Slightly more, (25, 13%), of the DS children went to a hospital for relief care than did the controls (12, 8%). Half of the parents were very appreciative of the relief care available, finding it provided a useful break for them and often a good experience for the child. However, 30% of both groups of parents were clearly dissatisfied with the services provided for their children.

Pre-school education. The pre-school educational opportunities for the children were different in the groups: 89 DS children and 37 controls had been to either a play group specifically for handicapped children or a nursery in a special school ($\chi^2 = 15.35$, d.f. = 1, $P < 0.001$). Conversely, 70 of the controls and 55 DS children had been to an ordinary play group, catering for normal children ($\chi^2 = 10.67$, d.f. = 1, $P < 0.01$). However, an additional 17 DS children and four controls had had the advantage of both sorts of pre-school provision.

Early intervention for handicapped children had only just become available when these children were small. 11 of the DS children and eight of the controls had been visited regularly by a teacher or counsellor in the first five years. None of the DS children who had had some early intervention had adaptive behaviour scores significantly below the average for the age-group but four had behaviour disorders and a further four were in the borderline group. The children in the control group given early intervention included three multi-handicapped children with very low adaptive behaviour scores and much deviant behaviour; only one child in this group had no behaviour problems.

Adaptive behaviour and parental psychiatric illness: Parents with psychiatric disorder were not more commonly found

in those families where the child had very low AAMD Adaptive Behaviour scores. Neither was additional physical disability, indicated by a low score on the physical development sub-scale, nor a low language score associated with a higher incidence of parental psychiatric illness.

Parents' perception of behaviour problems in the retarded child: The parents thought that 29 (15%) of the DS children and 37 (25%) of the controls had significant behaviour problems. These figures are much lower than the numbers of children judged as having serious behaviour disorder from the rating scales and behavioural check-lists. Hyperkinetic or bizarre behaviour were the most likely types to have been seen as problems by the parents, but they were not especially likely to see the children with very low adaptive behaviour as also having behaviour problems. Mothers with psychiatric disorder themselves were more likely to perceive their DS children as having significant behaviour problems, but this was not so in the control group. In the borderline group, there were four DS children identified by parents as having significant problems and two others in the group judged as normal. Three judged as 'borderline' and two as 'no disorder' in the control group were considered by their parents to have behaviour problems.

Factors associated with behaviour disorders: Behaviour disorder in the retarded child, as defined in the previous paper, were not related to family size, to age or educational achievements of the mother, to the physical health of either parent, or to relationships with members of the extended family. Neither was there evidence of association with social class, since the frequency of definite disorder was not significantly different in any social class in either group.

Three of the seven Down's children and three out of the four control children in the long-stay hospitals were found to have serious behaviour disorders. Disturbance was common also among those in local authority hostels, in five out nine DS children and in all three controls in hostels. By contrast, only one in eight of the fostered and one of the three adopted DS children had serious behaviour disorder. The adopted and fostered control children had more behaviour disorder, affecting all but one fostered child.

Behaviour disorders in the children and psychiatric disorder and quality of marital relationship of parents: Behaviour disorders in the controls were more frequent in the children whose parents' marriage was rated as moderate or poor than in those where it was rated as good (Table V). The same trend, to a lesser degree, could be seen in the DS families. There were fewest behaviour disorders in DS children of widowed or divorced mothers, with a clear difference between them and the children where the marriages were rated as moderate or poor, ($\chi^2 = 4.63$, d.f. = 1, $P < 0.05$). In the control group, the highest rate of disorder was found among children of widows, the rate in the

(Controls $\chi^2 = 4.1802$, d.f. = 2, NS)

divorced group being very similar to that found in association with poor marriages. Parental psychiatric disorder was most common in social classes IV and V, affecting 30% of families so classified in the DS group and 35% of families in the control group. Behaviour disorders in the retarded children in these social classes occurred just as commonly in families with well parents as in families with a psychiatrically ill parent. Psychiatric illness in the parents was likely to be associated with a poor marriage relationship. In the DS families with a good marital relationship,

parents with psychiatric disorder were more likely to have a retarded child who had a behaviour disorder, although the numbers in this group were small. In the context of a moderate or poor marriage, there was no demonstrable association between parental psychiatric disorder and behaviour disorders in the DS children themselves. Similarly, there was no strong association of parental psychiatric illness with behaviour disorders in the control group, except where there was severe mental disorder in the mother or father (Table VI).

Discussion

There was greater maternal age and a higher level of maternal education, with a bias towards upper social class, in the families of the children with DS. In this study, the older mothers included a significant proportion of women with degrees or professional training which had necessitated postponement of child bearing. Younger children with DS tended to come from smaller families, unlike those formerly typical—usually in social classes IV and V—where a child with DS would be born at the end of a long sibship. The social class distribution of our controls did show an opposite bias towards social classes IV and V, as has been reported in other recent studies of the family background of retarded children (Cooper & Lackus, 1984).

We found no evidence that older mothers were more vulnerable than younger ones, or that they were less effective in rearing these difficult children. There was less support from grandmothers in the DS group, which can be explained on grounds of age, as these older mothers did not themselves have mothers capable of offering them support.

The comparatively easy recognition of DS influences decisions made not just by the families themselves but by the community on how the child is reared, as is seen in the preschool period. The children are set off on a different pathway early in life, long before any objective measure can be made of the extent of intellectual impairment.

There is little evidence from this study to support the idea that bringing up a child with DS is markedly less stressful than rearing one with mental retardation due to other causes, although indications of other social problems were seen in the control families. No large differences in morbidity emerged among the parents in the two groups. Divorces were more common in the control group, although the quality of those marriages where husband and wife remained together differed little.

The incidence of psychiatric disorder in both groups of fathers was not markedly higher than that found in the general population, of whom 10.9% in surveys using the PSE have sufficient symptoms to be regarded as 'cases' (Wing *et al.* 1981). The higher incidence in the mothers can be interpreted as supporting the theory that they carry most of the burden and show most ill-effects. However, even the finding of 24% is not dissimilar to those of maternal disorder in families bringing up normal children under difficult circumstances (Brown & Harris, 1978; Richman *et al.* 1982).

Unhappy marriages are clearly associated with psychiatric disorder in parents in this group, and

both adverse effects occurred most frequently in the socially deprived families, in social classes IV and V. A mentally retarded child and an unhappy marriage in poor social circumstances add up to a high level of adversity (Pahl and Quine, 1984). There is a stronger association between behaviour disorders in the retarded child and marital discord in the control group than in the DS group.

The two groups of siblings of handicapped children had very similar rates of disturbance at home, but there was a difference, although not a large one, at school where the siblings of the control group were more often rated as deviant. An earlier finding, (Gath, 1974) that older sisters were particularly vulnerable has not been replicated in this study, ten years later. At that earlier time, their vulnerability was thought to be possibly due to the excessive burden of domestic responsibility. Improvements in provision for mentally retarded children may have contributed to the disappearance of sisters as a particularly vulnerable group, but in the 1974 study of siblings, 14 out of 89 sisters (16%) and 22 out of 85 brothers (26%) of children with DS were rated as deviant, using the same behavioural rating scales. In the present study, deviant scores were obtained by 25% of sisters and 23% of brothers. An alternative explanation might be that over the years, deviancy among all girls, including the sisters of DS children, has caught up with that previously found only in boys.

The behaviour disorders in the DS children showed a close association with psychiatric disorder in the siblings, as defined by deviant scores on either of the two Rutter scales. However, no such association was noted in children and siblings in the control group. A more detailed comparison of the retarded child/sibling pairs will be the subject of a further paper.

Parents appeared to show a remarkable degree of tolerance towards abnormal behaviour in their retarded children. Using objective measures, many more children were found with serious behaviour disorders than had been identified as such by their parents. Many parents regarded behaviour difficulties as an integral part of the handicap, and their attitude was one of resignation rather than tolerance. Psychiatrically disordered mothers of DS children did tend to perceive their children as having behaviour problems, whether they actually had them or not.

In child psychiatric literature, the association between parental psychopathology and childhood psychiatric disorder is well known. Various explanations have been suggested—genetic, based on family studies (Crowe 1983) and adoption studies

(Bohman, 1978) and environmental, the latter with particular emphasis on the effects of marital discord which often accompanies parental psychopathology (Quinton & Rutter, 1985). Most published work on families of handicapped children, particularly those who are mentally retarded, looks at the problem from the opposite point of view—that the child's disturbing behaviour is the cause of 'stress' to the parent, and hence of the symptoms, both physical and mental, which may result. Stress in our DS families is shown by the mother's perception of the child's behaviour as a problem.

Behaviour disorder in the DS child in this study was as common in social class II as in IV and V. This certainly does not fit with the findings on children in the normal range of intelligence, and is more in keeping with the hypothesis that in families with a retarded child the development of a behaviour disorder in that child is related to factors within the child rather than to environmental influences, especially within the family. A retarded child with a behaviour disorder in the home is certainly stressful, but psychiatric disorders in the parents studied by us, particularly the mothers, bore no simple relationship to the presence of behaviour disorder in the child, any more than they did to other measures of handicap. Other social problems compound this issue in the most deprived families, where the greatest ill-health and marital misery is found, but different factors must be operating in classes I and II.

The longitudinal study (Gath, 1977) showed that effects on a marriage occurred very soon after the birth of a child with DS and our follow-up of the families of children first seen in infancy indicates that behaviour disorders are likely to develop in families which have long-standing problems. In the present study, families where both parents were well and had a good harmonious marriage were in the minority in both DS and control groups, but where they occurred, they did so irrespectively of the ages and sexes of the affected children.

However, family influences alone can by no means explain the development of behaviour disorder either in children with DS or in controls. In the longitudinal study, communication problems with marked speech delay were found to be closely related to behaviour disorders, as also was general severe retardation. Both groups of children in this present study have been assessed using Adaptive behaviour scales and more detailed psychological testing of the DS children has also been carried out. These findings will be further analysed in relation to behaviour disorders in a later paper.

Conclusion

The family backgrounds of children with Down's syndrome have somewhat different socio-demographic features from those of other children with a similar degree of intellectual retardation. These differences can be summed up as a bias towards relative social advantage and easy parental recognition of the handicap in contrast to an opposite bias towards social deprivation and parental uncertainty in the control group whose retardation resulted from various known and unknown causes.

In our previous paper, the myth of the child with DS being an easy child was found not to be valid, so the apparent advantage of early diagnosis and the higher chance of being born to more educated parents does not spare the majority of families from the initial grief or long years of very hard work involved in rearing them. Marital discord is common and is associated with behaviour problems in the retarded child. This was even more true in the families of our control children than in families of those with DS. The finding that psychiatric morbidity is higher than in the general population in mothers, but not in fathers, in both groups suggests that the carer, usually the mother, has a heavy burden and is at risk of developing psychiatric disorder. That the risk is much the same for other women rearing children in difficult circumstances does not detract from the importance of this finding, since the others are likely to improve as their children grow up, whilst mothers of mentally handicapped children will face an even greater problem as their children leave school but not home. The options are least for those children who are doubly handicapped by difficult behaviour as well as mental retardation. Families who would be able to cope adequately with the demands of ordinary family life are now being asked to take on an exceptional role with no time off for an indefinite period. Even the most stable and healthy families require more help from outside than is easily available at present. Those with additional problems will need the services even more desperately but may be less able to obtain the help to which they are entitled. Services, therefore, must be sufficiently flexible to be able to respond to individual needs but this must not be at the expense of either the self-respect of the family or the well-being of the child.

Psychiatric Disorder in the General Hospital

R. MAYOU and K. HAWTON

There have been many reports of psychiatric disorder in medical populations, but few have used standard methods on representative patient groups. Even so, there is consistent evidence for considerable psychiatric morbidity in in-patient, out-patient and casualty department populations, much of which is unrecognised by hospital doctors. We require a better classification of psychiatric disorder in the general hospital, improved research measures, and more evidence about the nature and course of the many different types of problem so that we can provide precise advice for their management of routine clinical practice.

Psychiatric problems in general hospital patients are important, both because they are often easily treated and because they can also affect the course of medical conditions. However, it is uncertain which disorders benefit from extra treatment and how common these are in the various types of medical population. Most psychiatric research in the general hospital has been concerned with specific types of physical disorder, but we also need to know the overall prevalence of psychological problems in general hospital units as a basis for planning services, including liaison psychiatry, to meet clinical needs. In this review we examine the various forms of psychiatric disorder seen in the general hospital, and discuss their prevalence, clinical significance and the implications for management. We do not cover findings from hospital-based primary care, both because there is a large separate literature (see Goldberg & Huxley, 1980; Cavanaugh & Wettstein, 1984) and because the issues involved are somewhat different.

Research methodology in general hospital surveys

To obtain a full picture of psychiatric disorders in the general hospital, we need to know: the extent and nature of psychiatric morbidity; its relationship to the different types of physical illness; the degree to which it reflects a long-term history of psychiatric disorder or current social problems, or is more specifically related to the physical illness or hospital admission; and the medical, psychological and social outcomes. Unfortunately, there have been relatively few studies comparable to the extensive research examining these same issues in primary care (Goldberg & Huxley, 1980). Research in the general hospital has largely been of poor quality, failing

to describe adequately the medical populations surveyed or to use an adequate nomenclature or standard measures (Cavanaugh & Wettstein, 1984).

The characteristics of the medical population

Geographical, social and medical factors mean that there are considerable differences between hospitals in the nature of referrals and admissions. Few reports have adequately described the populations studied, in terms of age, sex, social class, types of medical problem and source of referrals. Some studies provide point or period prevalence, while others are surveys of admissions or new attenders. Not only are there differences between hospitals, but the pattern of medical care within hospitals is changing rapidly. For example, between 1972 and 1983 the proportions of emergency and elderly patients admitted to a medical unit in Oxford have greatly increased and the length of stay decreased (Maguire *et al*, 1974; Feldman *et al*, 1986).

In most studies it is not clear what efforts have been made to obtain information on patients who refused or were too ill to be interviewed, or whether they have been included in the analyses. Exclusion of such patients causes an under-estimate of psychiatric morbidity, since they are likely to have a relatively high prevalence of disorder—especially organic mental states (Feldman *et al*, 1986).

Nomenclature and case definition

A fundamental problem is that psychiatric classification and concepts are almost entirely based on research with psychiatric in-patients, and there has been little attempt to adapt them for use in general populations, primary care or the general hospital

(Williams *et al*, 1980; Goldberg, 1981; WHO, 1983). It is particularly difficult to distinguish between 'appropriate distress' and affective disorder, especially in the presence of medical symptoms. There are no generally accepted criteria for organic disorders and substance abuse. It is also common to see other patients who are not psychiatrically ill but who require extra help because their personality or behaviour is thought to be maladaptive—non-compliance, for instance, and some cases of deliberate self-harm. New methods of clinical classification are required if we are to define and sub-classify problems that need extra help.

Further difficulties arise because it is uncertain whether measures developed in specialist psychiatric populations can be used in the same way with patients who are physically ill. Even if simple screening instruments can be successfully adapted for epidemiological research, they may be less useful in clinical 'prescriptive' screening, which should be accurate enough to identify all those who may require further intervention (Skuse & Williams, 1984).

Affective disorder

Standardised measures

Most surveys have relied on simple screening methods, but a minority used two-stage procedures in which all screened 'cases' were interviewed. Earlier studies used unstandardised interviews or scales (see Cavanaugh & Wettstein, 1984), whereas most recent reports are based on established psychiatric procedures. Unfortunately, none have been adequately validated for use with the physically ill (Williams *et al*, 1980) and research in general practice has shown that there are considerable difficulties in identifying affective disorder in the presence of physical symptoms or illness (Goldberg & Huxley, 1980). On the one hand, standard procedures fail to detect 'masked' depression and anxiety in patients who 'deny' their emotional distress; on the other hand, they over-estimate disorder, because many patients have physical causes for fatigue and other somatic symptoms which are prominent items in all instruments used to detect emotional disorder. The recently described Hospital Anxiety and Depression scale (HAD) is the first to be designed specifically to avoid these problems (Zigmond & Snaith, 1983).

Subclassification into the specific diagnostic categories is often inappropriate, and it would be more useful to use a clinical classification similar to that proposed for primary care by Goldberg (1981):

- (a) major psychiatric illness—a small group which broadly corresponds to psychotic illness, and responds to physical treatments

- (b) psychological distress syndromes not requiring intensive intervention; some of these are transient reactions to events such as physical illness. For these, simple exploration, discussion and advice may be helpful

- (c) psychological distress syndromes which may require some form of more active intervention, such as drug treatment or social or psychological help.

These same groups are also apparent among patients with psychiatric morbidity in the general hospital, although there has so far been little attempt to distinguish between transient and persistent distress. It is to be hoped that eventually these difficulties of case definition will be resolved by the introduction of a multiaxial classification which will enable psychological syndromes, physical illness, social problems, and perhaps personality, to be coded on separate axes (Goldberg, 1981; Williams *et al*, 1980; WHO, 1983).

We consider below examples of three types of standard measure—self-report screening questionnaires, standardised clinical interviews, and symptom rating scales.

General Health Questionnaire (GHQ). This is by far the most popular screening instrument, in its full 60 item, or abbreviated 30 and 28 item versions (Goldberg, 1972; Goldberg, 1978). The 30 item version (GHQ-30) has often been preferred as being the least dependent on somatic symptoms. Since the GHQ is based on recent change in an individual's psychological state, it does not identify all patients with chronic disorders, and Goldberg (1983) now recommends two extra questions about use of psychotropic medication and history of nervous problems. A practical problem is that many elderly, confused and seriously ill patients find it difficult to complete the questionnaire, although this can often be overcome by reading out the questions.

Goldberg has always emphasised that calculated specificity and sensitivity depend on the nature of the screened population and that optimal discrimination depends on the correct choice of threshold (Goldberg, 1985). It is apparent that in medical populations both sensitivity and specificity are low, especially in the most severely physically ill groups (Table I). The high proportions of false positive cases are usually attributed to a number of items which are commonly answered by those who have physical symptoms or disabilities. It is possible to improve specificity by raising the cut-off threshold, but this reduces sensitivity. In most studies, GHQ negative subjects were not further assessed; the

TABLE I
 Characteristics of GHQ when used on general hospital patients

Form of GHQ	Reference	Population	No. of cases screened	Criterion	No. of interviews	Threshold	Sensitivity: %	Specificity: %
GHQ-60	Goldberg (1970)	Gastrointestinal out-patients	91	CIS	91	11/12	80	93
	Maguire <i>et al</i> (1974)	Medical admissions	230	CIS	77	11/12	90	58
	Kirk & Saunders (1979)	New neurology out-patients	342	CA ¹	342	11/12	66	59
	Byrne (1984)	New gynaecology out-patients	211	PSE	35	26/27 4/5	40 67	85 86
GHQ-28	Rabins & Brooks (1981)	Multiple sclerosis out-patients	150	PSE	25	4/5	92	92
	Bridges & Goldberg (1984)	Neurology admissions	100	CIS	70	4/5	100	57

	Feldman <i>et al</i> (1985)	Medical admissions	382	PSE	200	6/7 4/5	89 93	80 63
	Tyrer (1986)	Pain clinic	97	PSE	97	4/5	87	27

1 Clinical assessment

figures for false negatives depend only on review of medical notes and must be under-estimates.

We conclude that although the GHQ is the best available screening instrument for affective disorder, it is of limited value in the general hospital because it cannot by itself provide an estimate of prevalence until it has been validated for the particular medical population. Furthermore, it must be accepted that when used in a two-stage procedure there will be many false positives. In 'prescriptive screening' there is the additional problem that the sensitivity is too low to detect all those in need of further care (Skuse & Williams, 1984).

Other general screening tests. Goldberg (1985) has reviewed several other tests, some providing general scores and some subscores for specific symptoms. Only the Hospital Anxiety and Depression (HAD) scale has been derived from clinical experience to detect significant psychiatric disorder among medical patients (Zigmond & Snaith, 1983). Further research is required to determine the applicability of these tests.

Clinical Interview Schedule (CIS). This interview, developed for general practice research (Goldberg *et al.*, 1970), is sensitive to the psychiatric symptoms seen in general hospitals and acceptable to patients. Unfortunately there is no single accepted procedure for case definition, which can be based on an arbitrary total score, or on psychiatric judgement, or on a combination of both methods. It lacks the standardisation, computer program and comparability of the Present State Examination, but is more sensitive to less severe symptoms.

Present State Examination (PSE). World-wide use and standardisation are the major advantages of this instrument (Wing *et al.*, 1974), allowing comparison with general populations (Bebbington *et al.*, 1981; Henderson *et al.*, 1979) and with other psychiatric and medical groups. There are detailed rules for rating neurotic and psychotic symptoms, but no more than token questions for cognitive impairment and substance abuse. It can be a lengthy interview, requires skilled experienced interviewers, and does not allow rating of lesser degrees of emotional distress, since symptoms are only rated if 'clinically fairly severe'.

Some of the questions are awkwardly worded for use with the physically ill. Particular problems arise when rating 'understandable' distress apparently related to the physical disorder, since the instructions

state that 'appropriate' distress should not be rated. For general hospital use it is probably best to make explicit amendments to the PSE instructions. The CATEGO programme enables classification into diagnostic categories, and case definition is based on the total symptom score or, more satisfactorily, on the computed Index of Definitions grading of severity. The PSE case definition is more stringent than many other procedures. For example, in an Edinburgh community samples, Dean *et al.* (1983) found 8.7% of the sample were psychiatric cases with the PSE and 13.7% when Research Diagnostic Criteria (Spitzer, 1978) were used.

DSM-III. Although DSM-III was not designed to be an epidemiological instrument, it has been used in a number of general hospital surveys. However, the diagnostic rules are insufficiently precise for acceptable reliability. Furthermore, despite the general advantages of multiaxial classification, DSM-III categories have not proved entirely satisfactory for clinical use in the general hospital (Mackenzie *et al.*, 1983; Leigh *et al.*, 1982).

Screening tests for depression. Few of these procedures have been validated for use with the physically ill. The Beck Depression Inventory (BDI) has been the most widely used scale, and has proved acceptable in general hospitals but has not been standardised for this use (Beck *et al.*, 1961). It contains some somatic items, and this means that with the normal cut-off it identifies a rather high proportion of subjects as being mildly depressed (Moffic & Paykel, 1975; Clark *et al.*, 1983). The non-somatic items appear to discriminate well between depressed and non-depressed medical patients (Clark *et al.*, 1983). However, there are disadvantages in using the Beck and other mood scales to rate a single dimension of affect in populations in which undifferentiated emotional syndromes are more common than more specific forms of anxiety or depression.

There is no simple screening procedure suitable for routine clinical use by general hospital staff. However, there are several symptoms included in routine history taking which suggest possible affective disorder (e.g. lack of energy, insomnia, poor appetite, weight loss, memory disturbances, poor concentration, non-specific aches and pains, and bowel disturbances). Careful observation to detect emotional withdrawal and retardation or agitation, together with a few additional questions about mood, attitude to the future, interest in social and domestic life, libido, previous history of treatment

TABLE IV
Factors associated with affective disorder in general hospital patients

<i>Factor</i>	<i>Association and references</i>
Age	More common in younger patients ^{1,3}
Sex	More common in women. ^{1,4} No relationship ^{2,3}
Social class	Associated with lower social class in women ¹
Marital status	Associated with dissatisfaction with living alone ¹
Severity of physical illness	Associated with severe illness. ² Trend for association with severe, acute or chronic ¹
Absence of physical diagnosis	No clear relationship to physical diagnosis ^{1,2} Associated in out-patient series ⁵⁻⁸
History of psychological problems	Associated with previous psychiatric history, ^{1,2} psychotropic drugs and admission ^{1,8}
Social problems	Associated with social problems reported both by patients and by their general practitioner ¹ Associated with unemployment in men, problems in housing, finance, social life ¹

1. Feldman *et al* (1986); 2. Moffic & Paykel (1975); 3. Cavanaugh (1983); 4. Bridges & Goldberg (1984); 5. Mayou (1973); 6. Vazquez-Barquero *et al* (1985b); 7. Kirk & Saunders (1979); 8. MacDonald & Bouchier (1980)

for emotional problems and any major social difficulties, will allow detection of the majority of patients with significant mood disorders. Information from relatives, general practitioners and other informants and nursing observations is helpful.

Prevalence of affective disorder

Cavanaugh & Wettstein (1984) have reviewed the earlier literature and Table II and III summarise more recent reports. Surveys which used the GHQ alone report high figures, whereas those based on two-stage procedures report lower prevalences. Emotional disorder is mainly of moderate severity (Moffic & Paykel, 1975; Cavanaugh, 1983; Feldman *et al*, 1986), but both psychiatric disorder and sub-clinical distress are considerably more common than in the general population (Feldman *et al*, 1986). Some reports have considered anxiety and depression separately (see Cavanaugh, 1983) but we believe that, as in primary care (Goldberg & Huxley, 1980; WHO, 1983), the commonest pattern of affective disorder is an undifferentiated neurotic syndrome, which would be classified as adjustment disorder in DSM-III (Derogatis *et al*, 1983), and that only a small, but important, minority suffer from more specific psychiatric disorders. Moffic & Paykel (1975) compared the depressive symptoms of medical patients with those in psychiatric populations and found more pessimism and hopelessness but less

suicidal ideation. The limited evidence on associations with demographic, type of medical illness or other variables (Table IV) suggests that these are similar to the associations described for general populations.

Little is known of the prognosis of psychiatric disorder identified in the general hospital. Hawton (1981) found that psychiatric disturbance often persisted, especially in patients with a previous history of psychiatric disorder. The only study in which patients with psychiatric disorders were interviewed again after discharge found that most patients were improved at four month follow-up, but that a chronic course was associated with evidence of a previous history (Feldman *et al*, 1986). There is some evidence that psychiatric disorder is associated with poor prognosis for the medical condition (Querido, 1959; Moffic & Paykel, 1975; Hawton, 1981), although it is unclear whether this is because the psychiatric condition hinders recovery or because psychiatric disorder is associated with more severe conditions. The findings of Moffic & Paykel suggest the latter interpretation.

We conclude that although the methods used have often over-estimated the prevalence of affective disorder in the general hospital, disorders of moderate severity are considerably more common than in the general population, especially in younger women. They are often associated with evidence of long-standing psychological or social difficulties, but are

usually of good prognosis. These conclusions are supported by studies of patients with particular problems, e.g. myocardial infarction (Lloyd & Cawley, 1983), chronic intestinal disorders (Goldberg, 1970), admission for hysterectomy (Gath *et al*, 1982), chest pain (Bass & Wade, 1984) and cancer (Greer, 1985).

What are the clinical implications of these disorders? Some are distressing yet undiagnosed major psychiatric conditions, likely to respond to appropriate treatment. Some will severely complicate the management of physical illness. However, others (perhaps the majority) are transient states secondary to hospital admission or the physical condition, and may be expected to resolve soon after discharge. It remains uncertain which types of affective disorder benefit from recognition and treatment. When the condition appears severe, or where there are diagnostic or management difficulties, a psychiatric opinion can be helpful. The majority of patients probably require no more than support and simple help, although it is also sensible to inform the general practitioner so that he can reassess the psychological state.

Organic disorders

Standardised measures

There are no precise criteria for acute and chronic organic conditions, and it is difficult to distinguish mild impairment from normal functioning, especially in the elderly, the educationally and socially disadvantaged, and the distressed physically ill (WHO, 1983; Cooper & Bickel, 1984; Henderson & Huppert, 1984). There are three main approaches to screening for organic disorders: psychometric scales, brief clinical rating scales, and behavioural rating scales for use by nursing staff (see Cooper & Bickel, 1984; Henderson and Huppert, 1984).

Psychometric assessments, by means of tests such as the Weschler Adult Intelligence Scale (WAIS) (Weschler, 1955) or specific measures of memory, are useful in individual cases when close scrutiny is required in order to make a specific diagnosis. However, they are not suitable in general hospital surveys as they are time-consuming, require special skills to administer, and may prove unacceptable, especially to some cognitively intact subjects (Cooper & Bickel, 1984).

Mini-Mental State (MMS). This is the best known brief rating scale, consisting of thirty items which

assess orientation, registration, attention and calculation, recall, and language, and is based on answers to standard questions and performance of simple tasks (Folstein *et al*, 1975). It is brief, easy to use, and acceptable to most patients. Validity assessed against the WAIS appears to be good, but the ability of the MMS to detect mild dementia is unclear (Folstein *et al*, 1975). Using a psychiatrist's standardised clinical assessment, Anthony *et al* (1982) found reasonable sensitivity (87%) and specificity (82%) in the detection of cognitive impairment. False positives were more likely among poorly educated individuals and older subjects, so that while the specificity below the age of 60 was 92%, above 60 it was only 65%.

The MMS is a clinically useful instrument for the detection of poor cognitive function, but does not enable distinction between dementia, delirium, low intelligence and poor education. It is too lengthy for use with every patient.

Cognitive Assessment Schedule (CAS). This scale, a sub-scale of the Clifton Assessment Procedures for the Elderly (Pattie & Gilleard, 1979; McPherson *et al*, 1985), is similar to the MMS in that it includes specific orientation and information questions and performance items. It is brief, consisting of only 12 items, appears to have been satisfactory in general hospital surveys (Johnston *et al*, 1986; Feldman *et al*, 1986) and could easily be used in everyday clinical practice. When both the MMS and CAS were evaluated against psychiatrists judgements, the CAS was found to yield far fewer false positives (Johnston *et al*, 1986).

Standardised interviews. A number of standardised interviews have been developed to provide a more accurate and detailed psychiatric assessment, the best known being the Geriatric Mental State (Copeland *et al*, 1976) and the Comprehensive Assessment and Referral Evaluation (CARE) developed by Gurland *et al* (1977). Both are lengthy procedures and neither has yet been adequately assessed for reliability and validity in medical or other populations. The Geriatric Mental State is a standardised, semi-structured interview based on items from the PSE and the Psychiatric Status Schedule (Spitzer *et al*, 1970). There is a computerised diagnostic system (AGECAT).

In conclusion, several standardised measures are now available for the detection and assessment of organic disorders (Nelson *et al*, 1986). For large-scale surveys of general hospital patients either the MMS or the CAS can be recommended, although neither provides specific diagnostic information.

TABLE V
Studies of cognitive disorder in the general hospital

<i>Reference</i>	<i>Population</i>	<i>No. of patients</i>	<i>Case definition</i>	<i>Cases. %</i>
Bergman & Eastham (1974)	Admissions aged 65 or over to acute medical ward	100	Clinical assessment and memory tests	Dementia 7
Knights & Folstein (1977)	Medical ward admissions (mean age 55)	57	MMS (<23)	Delirium 10 33
De Paulo <i>et al</i> (1980)	Neurology admissions (mean age 50)	126	MMS (24)	30
Anthony <i>et al</i> (1982)	Medical ward admissions (29% aged >60)	97	MMS (<24) Clinical interview	33 Dementia 13 Delirium 9 Delirium + dementia 1
Cavanaugh (1983)	Medical in-patients survey (37% aged >65)	335	MMS (<23)	28
Bridges & Goldberg (1984)	Neurology admissions (mean age 45)	121	Clinical assessment and cognitive tests	2
Roca <i>et al</i> (1984)	Medical admissions (46% aged over 65)	380	MMS and psychiatric assessment	Dementia 15
Feldman <i>et al</i> (1986)	Medical admissions	453	CAS and review of notes	<70 years 2 >70 years 27

They require a second-stage method of assessment, preferably using an objective observer-rated method, or clinical assessment, in order to establish specific diagnoses and severity. In clinical practice, screening for organic disorders can be restricted to patients in the older age groups. Unless the routine history suggests difficulties, the CAS scale appears to provide a reasonably reliable method of screening, and can be recommended for this purpose. The MMS is valuable for more detailed assessment.

Prevalence of organic disorders

Table V summarises recent reports on the prevalence of organic disorders in general hospital in-patients, the majority of which have used a single screening instrument rather than a two-stage procedure. Unfortunately, most published reports have excluded a number of patients who were too ill for interview, many of whom were probably cognitively impaired (Feldman *et al*, 1986). Surveys using the MMS of patients of all ages admitted to general medical wards have yielded surprisingly consistent findings, with between a quarter and a third showing intellectual impairment. Few surveys have

examined the association of prevalence with age, but not surprisingly, organic mental disorders are especially common among older subjects (Bergman & Eastham, 1974; Feldman *et al*, 1986; Johnston *et al*, 1986). In neurology patients, abnormal MMS results are usually found in those with cerebral rather than peripheral disorders (De Paulo & Folstein, 1978).

In a study of 100 referrals to a consultation service, Cutting (1980) found it difficult to establish the specific cause of cerebral dysfunction in the majority of the 74 patients with acute organic psychiatric disorder. However, Hodkinson (1973), in a large multi-centre study of elderly patients, concluded that factors predisposing to delirium were dementia, defective hearing and vision, parkinsonism, and advanced age; precipitating factors were pneumonias, cardiac failure, urinary infection, carcinomatosis, and hypocalcaemia in particular, and severe illness in general.

There is little evidence concerning the prevalence in the general hospital of the various organic syndromes: delirium, dementia and delirium plus dementia. The importance of such distinctions was emphasised by Rabins & Folstein (1982), who found significantly higher death rates for delirious patients

compared with those with dementia, during hospital admission and at one year follow-up. Several accounts of referral to consultation-liaison services have also described the high mortality of those with delirium (Ruskin, 1985; Rabins *et al*, 1983; Popkin *et al*, 1984).

Recognition of organic mental disorders has major practical implications. Mistakes in the differential diagnosis of organic and affective disorder (Hoffman, 1982; Dubin *et al*, 1983) and misdiagnosis of dementia in the unimpaired elderly and the poorly educated (Roca *et al*, 1984) may result in inappropriate treatment and referral. The early identification of delirium is extremely important, because it may be life-threatening and require immediate treatment of the underlying physical disorder. Furthermore, delirious patients are often distressed and can be difficult to manage, yet appropriate psychiatric treatment is usually rapidly effective (Lipowski, 1983). Dementia has implications for continuing care. Johnston *et al* (1986) found that cognitively impaired patients stayed significantly longer in hospital than the unimpaired, an important reason being lack of suitable accommodation. Cognitive impairment limits compliance with medication, because of failure to remember dose schedules, especially when more than one drug is prescribed.

Alcohol

Screening procedures

The lack of any satisfactory classification of problem drinking and its complications (WHO, 1983, 1981) has limited study of epidemiology in the general hospital (McIntosh, 1982). Apart from detailed questioning about consumption (Midanik, 1982), there are two principal approaches: screening interviews and laboratory tests (Mayfield & Johnston, 1980; Holt *et al*, 1981; Bernadt *et al*, 1982). The first, and probably still the best known screening interview, is the Michigan Alcoholism Screening Test (MAST), which is available in 13 and 25 item versions (Selzer, 1971; Pokorny *et al*, 1972). A simple and attractive alternative is the four question CAGE (Ewing, 1984). These procedures have been shown to identify the majority of known alcoholics in a variety of psychiatric and other settings. However, specificity of screening is relatively low (Lancet, 1980; Bernadt *et al*, 1982; Holt *et al*, 1981), and none of the methods have been adequately validated in general hospital populations. There is no doubt that many patients who are known by physicians to have major alcohol problems are not detected, and also that screening questionnaires are not sensitive to early, and perhaps more treatable, alcohol problems.

Laboratory tests include blood alcohol, liver enzymes (aspartate aminotransferase; alanine aminotransferase, gamma glutamyl transpeptidase) and haematology (macrocytosis without anaemia). Individual tests and combinations can be helpful in identifying many patients who abuse alcohol (Lancet, 1980; Bernadt *et al*, 1982; Holt *et al*, 1981), although they are sometimes difficult to interpret and are insensitive to early drinking problems (Lloyd *et al*, 1982).

There are considerable advantages in using a procedure which combines screening interviews such as the CAGE and MAST with laboratory tests (Holt *et al*, 1981; Mayfield & Johnston, 1980). A promising research alternative is a detailed structured interview procedure covering the psychological, social and medical aspects of alcoholism, administered by a specially trained research worker (Lloyd *et al*, 1982; Chick *et al*, 1985).

Prevalence of alcohol problems

It is generally accepted that alcohol dependence and its complications are particularly common in medical populations. However, the evidence is confusing and unsatisfactory (McIntosh, 1982). There are considerable problems in interpreting published findings: the use of many different criteria for alcohol dependence; difficulties in defining alcohol-related disease, since all forms also occur in non-drinkers; failure to distinguish between active problems and those in remission; it is frequently unclear as to whether findings refer to alcoholism as the primary cause of the admission or as an entirely incidental finding; and few accounts state to what extent the findings in the hospital reflect particular characteristics of the local population.

Most surveys refer to general medical patients, and only a small proportion deal with surgical, orthopaedic, gynaecological or other medical groups (see McIntosh, 1982 and Table VI). In his very thorough review, McIntosh pessimistically concludes that: "It is still not possible to say, either precisely or even within what limits, what proportion of general hospital patients have alcohol-related disorders which are either causal or incidental to admission". It is probable that drinking problems are particularly common in emergency departments (Holt *et al*, 1980), accident and orthopaedic wards, and general medical units (Barrison *et al*, 1982), especially those specialising in gastroenterology.

Recognition of problem drinking is important both in immediate management and because of the greatly increased risk of future physical and mental ill-health, as well as social and domestic problems,

TABLE VI
Studies of alcohol problems in general hospital patients

Reference	Population	No of cases screened	Case identification	Problems: %
Barrison <i>et al</i> (1982)	Consecutive hospital admissions aged 18-65	520	Consumption and	16
		219	CAGE	23
Beresford <i>et al</i> (1982)	Consecutive acute injury admission to orthopaedic ward	87	CAGE and interview	14
Jariwalla <i>et al</i> (1979)	Admission to medical ward	545	Consumption and medical assessment	(alcohol related illness) 27
Holt <i>et al</i> (1980)	Evening attenders at an emergency department	702	Clinical assessment and blood alcohol	32 (blood alcohol > 80 mg/100 ml)
Lloyd <i>et al</i> (1982)	General medical admissions aged 18-65	275	Standard interview for current problems or previous treatment	Women 11 Men 27
Martin <i>et al</i> (1983)	Medical admissions	648	MAST, blood alcohol, medical assessment	20
Feldman <i>et al</i> (1986)	Medical admissions	453	Consumption, CAGE	Women 4 Men 18

in those who continue to abuse alcohol. While the results of treatment for alcoholism continue to be modest, sufficient numbers of individuals can be helped to make detection worthwhile. Intervention may be particularly effective in those whose alcohol consumption is excessive but not yet out of control (Skinner *et al*, 1981; Chick *et al*, 1985). In clinical care, there are no entirely satisfactory and simple means for detecting patients with problems in the use of alcohol. However, the four questions in the CAGE questionnaire, supplemented by simple questions about levels of alcohol consumption, awareness of the physical conditions commonly related to alcohol abuse (e.g. peptic ulcer, oesophagitis, head injury) and the blood test findings likely in alcoholics, will help in the detection of the majority of patients with serious drinking problems. It is sensible to concentrate on more intensive screening of high risk groups such as those attending emergency departments and liver clinics and those with predisposing occupations.

Other psychiatric problems

Several other types of psychiatric problems are more common among general hospital patients than in the general population.

Drug abuse

Although medical and psychological complications

of drug abuse are encountered in all parts of larger hospitals, studies in North America and Great Britain have concentrated on the prevalence of drug-related problems in accident and emergency departments. In a survey of seven London casualty departments (Ghodse, 1981) the rate of drug-related attendances in the casualty population was estimated to be 18.3/1000. They were predominantly young women, and at least 32% of individuals were dependent on drugs; 95% of attendances were for overdoses and 5% for reasons such as the complications of self-injection. Similar findings have been reported from the United States and Canada (Russe & Wells, 1980; Sellers *et al*, 1981; Maslansky, 1974). Drug dependence has been less well described in other medical populations, but narcotic and other drug dependence is particularly common in pain clinic attenders (Evans, 1981; Maruta *et al*, 1979).

Sleep disorders

There appears to have been no studies of sleep disorders in general hospital patients, but use of hypnotic drugs has received much attention. Reported rates of prescribing of hypnotics have varied from between less than a quarter of patients (Magni *et al*, 1984) to the majority (Perry & Wu, 1984). Prescriptions are usually on an 'as required' basis, with far fewer patients actually receiving them. Hypnotics are prescribed more often for the elderly

(Salzman & Van der Kolk, 1980; Mallings & Moon, 1983), for women, and for patients with relatively long admissions (Magni *et al*, 1984). Mallings & Moon reported greater use of hypnotics in medical than surgical patients, while Perry & Wu reported very much the reverse. Hypnotics are used particularly often in patients with malignant disease, those undergoing cardio-thoracic surgery (Mallings & Moon), and those recovering from surgery (Perry & Wu). Sleep disorders are likely to be associated with pain, and with anxiety and depression (Feldman *et al*, 1986), but noise and other environmental factors may have an important role (Berlin, 1984). Medication and drug withdrawal (especially alcohol) are also relevant.

A disturbing report from the USA by Perry & Wu (1984) suggested that the extent of hypnotic use provides little indication of sleep disorders in general hospital patients. None of the case-notes recorded the indications for hypnotics, and there was no correlation between nurses' notes of sleep patterns and prescription. They concluded that the "rationale for hypnotic agents in the general hospital is not clear".

The prevalence and causes of sleep disorders in general hospital patients, and the best means of managing them, is obviously an area for further investigation.

Sexual problems

The very common associations between sexual problems and medical and surgical disorders have been extensively reviewed elsewhere (Hawton, 1982; Bancroft, 1983). However, few systematic studies of specific conditions have been carried out, the main exception being diabetes. Approximately half of all men with diabetes will suffer erectile failure, due to either neuropathy of autonomic nerves or vascular disease, the proportion increasing rapidly with age (McCulloch *et al*, 1980; Goldstein *et al*, 1983). Sexual problems are also commonly associated with heart disease, renal failure, and peripheral neurological disorders. Numerous drugs used to treat medical conditions can have sexual side-effects, with anti-hypertensives being the worst culprits (Lancet, 1981). In contrast to the considerable information about the effects of physical illness and drug treatments on male sexuality, far less is known about their effects in women.

Although medical disorders and surgical procedures may cause sexual problems because of direct interference with anatomical or physiological mechanisms, psychological responses to illness are also important. Unfortunately, the latter have

undergone little systematic investigation, although numerous reports point to them as major factors.

Eating disorders

Similarly, there is virtually no information about the prevalence of eating disorders in general hospital patients. Although there have been some investigations of obesity and malnutrition, there is little indication of any associations with psychiatric morbidity. Obesity is common in medical patients, whether measured objectively (Abiin *et al*, 1982) or identified retrospectively from scrutiny of case-notes (Berger *et al*, 1977). Recent figures for the incidence have varied between 9% (Abiin *et al*) and 24% (Berger *et al*), although such variation is likely to be related to cultural factors, as well as methods of assessment. Malnutrition has been identified in at least one in five patients (Bistrian *et al*, 1976; Abiin *et al*, 1982), being particularly common in the elderly.

We are not aware of any studies of the prevalence of either anorexia nervosa or bulimia nervosa in general hospital patients, although they are described as reasons for referral to psychiatric consultation services. Case reports and surveys (Rodin *et al*, 1985) suggest that eating disorders may be especially common in diabetic clinics. Apart from severe weight loss and consequent malnutrition, anorexia nervosa may cause electrolyte disturbance, especially if associated with laxative abuse or vomiting. Similarly, there are important medical complications of bulimia nervosa, including acute gastric dilatation, oesophagitis, pancreatitis, and electrolyte disturbances (Harris, 1983).

Attempted suicide

Attempted suicide, especially deliberate self-poisoning, is the most common reason for acute medical admission in women, and in men it is second only to ischaemic heart disease (Hawton & Catalan, 1982). Following a rapid rise in such admissions during the late 1960s and early 1970s (Weissman, 1974; Wexler *et al*, 1978), the rates have recently levelled off and possibly declined, especially in women, although deliberate self-poisoning continues to be a major problem among young people (Hawton & Goldacre, 1982).

Widely varying prevalence figures of psychiatric disorders among attempted suicide patients have been reported, reflecting differences in diagnostic criteria. Two studies in which the PSE was used have helped to clarify the picture. Although psychiatric symptoms during the month preceding attempts are found in the majority of patients, Newson-Smith &

TABLE VII
Absence of physical diagnosis in new referrals to out-patient clinics

	Setting	No. of patients	% without physical diagnosis
Culpan & Davies (1960)	Medicine	100	38
	Surgery	100	5
Mayou (1975)	Venereal disease	100	34
Kirk & Sanders (1979)	Neurology	342	27
MacDonald & Bouchier (1980)	Gastroenterology	100	45
Hughes <i>et al</i> (1983)	Dermatology	100	1
Pearson (1985)	Allergy clinic	250	13

Hirsch (1979) identified 'definite' psychiatric disorder in only 31% using the PSE, with a further 29% being in the borderline or 'threshold' category. Almost all were suffering from depression. Similar findings were reported by Urwin & Gibbons (1979), although they also identified patients with alcoholism, anxiety states and schizophrenia. Other studies have found alcoholism to be particularly common in male attempters (Morgan *et al*, 1975; Holding *et al*, 1977).

There is a rapid decline in the prevalence of psychiatric disorder during the first few months after attempts (Newson-Smith & Hirsch, 1979), although it is unlikely that there is a significant change in alcohol problems.

Psychiatric disorder presenting with physical symptoms

Somatic symptoms without significant physical cause are regularly seen in general hospital wards, and are especially common in many out-patient clinics (Table VII) and in emergency departments. Psychiatric accounts of hypochondriasis are based on highly selected clinical experience, and there is no adequate classification (Barsky & Klerman, 1983; Lloyd, 1983). Atypical abdominal pain (Gomez & Dally, 1977; Drossman, 1982), chest pain (Mayou, 1973; Bass & Wade, 1984) and pain clinic attenders (Tyrer *et al*, 1986) have been well described.

Most patients are easily reassured, but a minority suffer persistent symptoms with psychiatric and social disability. Descriptions of referrals to psychiatric services (Katon *et al*, 1984; Slavney & Teitelbaum, 1985) show that most are suffering from primary affective disorder, although it is not uncommon for the more characteristic psychological symptoms to be 'masked'. Others suffer from what are classified in DSM-III (American Psychiatric Association, 1980) as somatoform, dissociative and

factitious disorders, and in a further small group there is no convincing psychological or social explanation. It is important to be aware that a proportion of such patients are eventually diagnosed as suffering from major medical illness.

Hysteria

Hysterical symptoms are undoubtedly common, though usually referred to as 'functional overlay'. The main evidence for the prevalence of syndromes of hysteria (conversion, dissociative states and Briquet's syndrome) comes from surveys of psychiatric consultations (see Ziegler *et al*, 1960; McKegney, 1967; Cavanaugh & Wettstein, 1984; Folks *et al*, 1984) in which up to 13% of patients referred to consultation services were diagnosed as having hysteria. Trimble (1981) reported that 1% of admissions to a specialist neurological hospital are given the diagnosis of hysteria.

Factitious disorder

The dramatic clinical picture of the Munchausen syndrome is uncommon. Blackwell (1968) identified ten cases in a London teaching hospital in one year. Patients with other forms of artefactual or factitious disorder are more common, and are more willing to accept psychiatric assessment and treatment (Carney & Brown, 1983; Reich & Gottfried, 1983; Bayliss, 1984). Reich and Gottfried described 41 cases, of whom 39 were women. Most had experience of occupations related to medicine, and there were four main clinical groups: self-induced infections, simulated specific illnesses with no actual disorder, chronic wounds, and self-medication. Reports of other patients with specific artefactual symptoms, such as dermatitis artefacta (Sneddon, 1983), pyrexia of unknown origin (Aduan *et al*, 1979), bruising

disorders (Ratnoff, 1980) and diabetes (Schade *et al*, 1985) suggest that factitious disorder is much more common than is normally recognised (see Bayliss, 1984).

Recognition of psychiatric disorder by medical staff

It has frequently been observed that hospital doctors and nurses seriously underestimate and misdiagnose all forms of psychiatric disorder (Table VIII). Although we do not doubt the general conclusion, there are serious flaws in some of the evidence. Most reports assume that the other screening instruments provide a satisfactory criterion for the 'true' prevalence of psychiatric disorder, but we have already seen that the GHQ has a low specificity in the general hospital and substantially over-estimates the prevalence. On the other hand, it is unreasonable to assume that case notes are a reliable guide to physicians' assessment.

The diagnosis of affective disorder is often difficult in the presence of physical illness. Goldberg & Blackwell (1970) found this was the main cause of 'hidden psychiatric morbidity' in a general practice study in which the general practitioner was an

experienced and qualified psychiatrist. Hospital doctors are no more likely to diagnose severe problems than mild ones, and when they do recognise psychiatric disorder they are unlikely to code it in case summaries (Feldman *et al*, 1985). It is expected that systematic enquiries about the non-somatic features of anxiety and depression would enable much higher rates of detection.

Cognitive disorder is often obvious but may be misdiagnosed as affective disorder (Hoffman *et al*, 1982; Dubin *et al*, 1983) or missed altogether. Roca *et al* (1984) compared the judgements of medical interns with psychiatrists' standardised diagnosis of dementia and found a sensitivity of 79% and specificity of 80%. The interns were just as likely to mis-diagnose dementia in unimpaired subjects as to fail to make a correct diagnosis. Use of systematic screening tests (Goldberg, 1985) and proper attention to age, educational status and evidence of previous function could be expected to improve recognition.

Surveys of alcohol problems have commented that doctors often fail to record the clinical history (Barrison *et al*, 1980) and that they underestimate both problems and consumption (Barrison *et al*, 1980; Lloyd *et al*, 1982). Westermeyer *et al* (1978) also

TABLE VIII

noted that physicians who were aware of problem drinking did not regard this as a medical concern, and did not see themselves as having responsibility for initiating treatment. Effective detection of alcohol problems requires a high degree of suspicion of high risk groups and the use of a combination of screening measures (Skinner *et al*, 1981).

Psychiatric disorder and medical settings

There are, undoubtedly, wide differences in the prevalence of psychiatric disorder in the many types of in-patient and out-patient units within the general hospital, but there have been few systematic studies and most epidemiological evidence derives from acute medical units. It is important that areas with a particularly high prevalence of psychiatric disorder be detected, since these must be the priorities for the provision of liaison psychiatry and other psychiatric and social services.

In-patients

Acute and chronic organic disorders are especially common in patients aged over 65 years (Bergman & Eastham, 1974; Lipowski, 1983), although they are much less commonly referred for psychiatric opinions than younger medical patients (Rabins *et al*, 1983; Popkin *et al*, 1984). Emotional disorder is more frequent in younger patients (Feldman *et al*, 1986) and is usually either of long standing or a reaction to acute illness and hospital admission. A small proportion of in-patients present with somatic symptoms due to primary psychiatric disorder.

Little is known of prevalence in other than medical and neurology wards. Psychiatric morbidity is probably particularly high in accident wards and in those specialising in the care of severe illnesses, often involving distressing treatment, for example cancer units (Derogatis *et al*, 1983; Bukberg *et al*, 1984), intensive care, radiotherapy (Forester & Kornfeld, 1978) and spinal injury wards.

Out-patients

This review does not cover hospital-based primary care as practised in North America and elsewhere (see Cavanaugh & Wettstein, 1984) and refers only to secondary care as is usual in Britain (Table II). In an early study, Culpan & Davis (1960) found considerable morbidity in patients attending general medical clinics and rather less in surgical out-patients. Short-term prognosis was relatively good, but 18% of medical patients and 5% of surgical patients were thought to require more psychiatric care than was

possible in a general out-patient clinic. Particularly high prevalence of psychological and social problems has been described in some specialist out-patient clinics, including cardiac out-patients (Vazquez-Barquero *et al*, 1985a,b), pain clinics (Tyner *et al*, 1985; Merskey & Spear, 1967), and clinics caring for severe chronic disorders such as renal failure (Czackes & De Nour, 1978), rheumatoid arthritis (Rogers *et al*, 1982) and diabetes (Tattersall, 1981).

We have already seen that patients without a significant physical cause of somatic symptoms are common in many out-patient clinics and that some of these patients may suffer from primary psychiatric disorder. These disorders are often easily treated, and it is unfortunate that they are frequently unrecognised and cause chronic disability. Research on specific patient groups suggest that current and previous psychiatric state are good predictors of psychosocial and possibly medical outcome in these patients.

Emergency departments

Affective and organic psychiatric disorder, substance abuse and other psychiatric problems are common in emergency departments, both as presenting problems and as incidental findings in those with physical diagnoses. Almost all detailed surveys have been restricted to the small minority of attenders seen by psychiatrists, or recorded by the consulting doctor as having psychiatric disorder.

In Britain, casualty doctors see all attenders and refer a proportion of those to duty psychiatrists (about 2% of all attenders). Bassuk *et al* (1983) reported that casualty doctors at the Bristol Royal Infirmary made a principal diagnosis of overt psychiatric disorder in 0.98% of attenders, of self-injury in 2.5%, and of physical symptoms with no specific physical cause in 2.5%. They made no comment on psychiatric disorder in those who had physical problems. In North America, preliminary assessment by nursing staff results in 3–5% of attenders being seen by the psychiatric emergency clinic. American reviewers have noted that over the past 10–20 years emergency departments have taken on increasing responsibilities for the management of chronic mental illness (Gerson & Bassuk, 1980; Bristol *et al*, 1981; Jones & Yoda, 1982). The nature of the psychiatric morbidity depends greatly on the area served (Jacobsen & Howell, 1978).

The only survey of consecutive emergency department attenders is that of Summers *et al* (1979), who assessed samples of 100 daytime attenders and 100 night-time attenders in an Ohio general hospital. Psychiatric disorder was identified in 26% of the

former and 65% of the latter. The most frequent diagnoses were alcohol problems and anti-social personality (29% and 17% respectively at night), with Briquet's syndrome, drug and alcohol dependence all being common. Salkovskis *et al* (1986) surveyed 149 accident and emergency department attenders in Leeds, having excluded deliberate self-harm, overt psychiatric disorder and the severely ill, and found that 36% scored above threshold on the GHQ or HAD scales.

Concluding comments

There is ample evidence that psychiatric morbidity is common in the general hospital. There are also hospital patients who do not have major psychological symptoms but who present management difficulties or are distressed by social problems, and who may benefit from psychological or social

intervention. There is a clear need to develop both a better classification of psychiatric disorder in the general hospital and appropriate research measures so that prevalence, nature and outcome of the various forms of disorder can be accurately described. Such basic epidemiological research should be accompanied by the evaluation of treatments leading to provision of better care for those who need it.

Sophisticated research measures are unlikely to be useful to busy general hospital staff. We have made suggestions about how they can detect the majority of patients who have significant psychiatric disorder. In particular, there is a need for greater awareness of the disorders that we have reviewed, together with systematic history-taking which has both psychiatric as well as physical diagnoses in mind. We believe that general hospital staff can detect their patients' more serious psychiatric problems and provide simple care without excessive extra demands on their time.

Modecate Abbreviated Prescribing Information. Indications: Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, pheochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices.** **Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 10 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.

TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept. Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients.

Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes. Most patients can be controlled with an injection at intervals of 3 weeks or more! Modecate is less expensive than other depot neuroleptics when comparing equipotent doses.

FROM CLINIC...

...TO COMMUNITY

CLOPIXOL[®]

zuclopenthixol dihydrochloride/zuclopenthixol decanoate

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.
Indications Psychoses.
Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 50mg/day in divided doses.
Children Not recommended.
Side-effects Extrapyramidal side-effects may occur and sometimes may require control by antiparkinson drugs.
Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics.
Warnings (a) Use with caution in patients

with Parkinsonism, severe arteriosclerosis, senile confusion states, serious renal, hepatic or cardiovascular disease.
Overdosage Overdosage should be treated by gastric lavage.
Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. PL Nos 0458/0027, 0028, 0029. PA Nos 115/5/3, 4, 6.
CLOPIXOL INJECTION & CLOPIXOL CONC. INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.
Indications Psychoses, especially schizophrenia

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.
Children Not recommended.
Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.
Contraindications Comatose states.
Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.
Further information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation

or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.
Package quantities & NHS price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23. PL Nos 0458/0017, 0041. PA Nos 115/5/1, 5, 7.

Conditioning and Sensitisation in the Longitudinal Course of Affective Illness

ROBERT M. POST, DAVID R. RUBINOW and JAMES C. BALLENGER

Few biological theories of manic-depressive illness have focused on the longitudinal course of affective dysfunction and the mechanisms underlying its often recurrent and progressive course. The authors discuss two models for the development of progressive behavioural dysfunction—behavioural sensitisation and electrophysiological kindling—as they provide clues to important clinical and biological variables relevant to sensitisation in affective illness. The role of environmental context and conditioning in mediating behavioural and biochemical aspects of this sensitisation is emphasised. The sensitisation models provide a conceptual approach to previously inexplicable clinical phenomena in the longitudinal course of affective illness and may provide a bridge between psycho-analytic/psychosocial and neurobiological formulations of manic-depressive illness.

Many of the current biological theories of manic-depressive illness have focused on the acute changes in affective states and on their possible underlying biological determinants. There has been less attention paid to the mechanisms underlying the longitudinal course of affective illness. We examined two different sensitisation models, behavioural and electrophysiological, which might help to conceptualise the progression of symptoms in recurrent affective illness. However, we do not propose that these models fulfil all the usual requirements for an animal model of mania or depression *per se* (McKinney *et al*, 1984).

Several aspects of the course of affective illness deserve further emphasis. First, both bipolar and unipolar affective illness tend to be recurrent in the majority of patients (Perris, 1966; Angst, 1978; Kraepelin, 1921; Grof *et al*, 1974; Zis & Goodwin, 1979). Secondly, the frequency of recurrence and rapid cycling increases not only with age, but as a function of the number of prior episodes (Kraepelin, 1921, Grof *et al*, 1974; Zis & Goodwin, 1979; Cutler & Post, 1982). Thirdly, similar symptoms tend to be reproduced in each episode with new ones added in sequential or stepwise fashion. Affective episodes later in the course of the illness may be more severe and have more precipitous onsets (Post *et al*, 1981a) than earlier episodes.

We hypothesise that a subgroup of patients becomes more vulnerable, or 'sensitized', to recurrences of affective episodes. We suggest that these patients show characteristics of a sensitisation or kindling-like process in which the biochemical and physiological processes involved in the illness

become progressively more easily triggered by the same circumstances or precipitants. Eventually, the episodes may occur spontaneously. Conditioned behavioural and biochemical changes might also occur, as demonstrated in laboratory studies. The models account for several phenomena observed in the course of affective illness; they suggest new avenues of research and stress the importance of preventing episodes with prophylactic treatment to inhibit sensitisation.

While there is still debate about the aetiological role of psychosocial stress in the onset of affective episodes, there is substantial evidence that for some patients environmental precipitants are associated with the onset of illness (Paykel, 1979a, b; Dunner & Hall, 1980; Brown *et al*, 1975; Amelas, 1979; Lloyd, 1980). Behavioural sensitisation could provide a model for the large subgroup of patients who develop more severe and rapid recurrences, in apparent response to repeated stresses of equal or reduced magnitude. Moreover, as patients develop increasing rapidity of cycling, the illness appears to evolve with its own rhythmicity and spontaneity, independent of ongoing life events. The mechanisms underlying such recurrent illness may be similar to kindling and behavioural sensitisation, as described below. Some patients have only a single affective episode. Genetic and environmental influences may be important in determining this pattern of non-recurrent illness; we will not address this subgroup further.

Kindling

Electrical kindling, as originally described by

Goddard *et al* (1969), refers to the development of major motor seizures in response to repeated intermittent electrical stimulation of the brain with insufficient current to produce overt behavioural effects (Racine, 1978). Recent data suggest that repeated application of some pharmacological agents, either parenterally or directly into the brain, may also produce a progressive increase in neural excitability, similar to kindling, eventually producing major motor seizures in response to a previously subthreshold dose of drug (Post & Kopanda, 1976; Post *et al*, 1982).

The intermittency of the stimulation appears to be critical for the development of amygdala-kindled seizures (Goddard *et al*, 1969; Racine, 1978; Post, 1980). Continuous amygdala stimulation or stimulation every 2–5 min is not associated with kindling; rather, the animal habituates and does not show major motor seizures. In contrast, intermittent stimulation at intervals longer than once every 2 hours (optimally, once every 24 hours or even once a week) is associated with the relatively rapid development of a convulsive response to the original subthreshold kindling stimulation. This temporal pattern of intermittent stimulation in the development of either tolerance or sensitisation may have parallel implications for the development of pathological behaviour in response to other intermittent stimuli, including stress (Post, 1980).

Kindling is a long-lasting, possibly permanent, change in neural excitability. Animals kindled in youth retain convulsive susceptibility in adulthood. As one ascends the phylogenetic scale, particularly in rhesus and human primates, kindling to a convulsive end-point appears to be increasingly difficult to achieve. Therefore, kindled seizures are only one marker of the development of the sensitisation process; many of the important characteristics of the kindling paradigm, including change in threshold and associated changes in behaviour (Adamec, 1975; Post, 1981; Post *et al*, 1984), can be observed in the absence of seizures.

After many repetitions of kindled seizures an animal may exhibit 'spontaneity', i.e. develop seizures in the absence of external stimulation (Pinel, 1981; Wada *et al*, 1974). The phenomenon of spontaneity has obvious importance for establishing kindling as a model of epilepsy. We suggest that kindling may help us understand how stress-induced mood alterations may become so sensitized that they also occur spontaneously; i.e. the rapidly or continuously cycling pattern of manic-depressive illness. It is pertinent that approximately one-third of kindled animals show cycling in their seizure patterns (Post, 1981).

Behavioural sensitisation

Repeated, intermittent application of psychomotor stimulants and dopaminergic agonists produces an increasing behavioural responsivity to selected end-points, such as motor hyperactivity or stereotypes. When sensitisation occurs, the behavioural changes develop with faster onset, increased magnitude and longer duration (Martres *et al*, 1977; Shuster *et al*, 1977; Segal & Mandell, 1974; Kilbey & Ellinwood, 1977). While behavioural sensitisation and electrophysiological kindling show similar progressive time courses, the mechanisms underlying these two phenomena appear to involve different neurotransmitter pathways (Post *et al*, 1982, 1985). The similarities and differences between kindling and behavioural sensitisation may help us understand the mechanisms underlying the progressive phenomenology of affective illness.

Conditioning appears to play a role in the development of behavioural sensitisation. For example, environmental cues associated with repeated cocaine exposure are important determinants of the degree of response to cocaine (Post *et al*, 1981b; 1985). Hinson and Poulos (1981) also found that the increased behavioural response to cocaine could be desensitized with saline injections. Behavioural sensitisation is modulated by peptide hormones, is more robust in females compared to males, shows cross-sensitisation to stress, and may involve a dopaminergic substrate (Post *et al*, 1984). A dopaminergic mechanism in behavioural sensitisation and its potential cross-sensitisation to stress (Antelman *et al*, 1980; Antelman & Eichler, 1979) suggest a link to the dopaminergic mechanisms in affective illness (Post *et al*, 1978; Jimerson & Post, 1984). The findings of Pickar *et al* (1984) also suggest that our model of drug-induced behavioural sensitisation may be extended to include the development of manic syndromes in man. Depressed patients who became manic during their first course of treatment with a monoamine oxidase inhibitor (MAOI) consistently became manic earlier in the course of a second treatment with an MAOI than on the first occasion. We postulate that a similar sensitisation may occur in non-drug-induced episodes.

Stresses of particular type, intensity, and intermittency may produce sensitisation in a fashion similar to the behavioural sensitisation described above. Sklar & Harris (1985) reported that intermittent or temporary loss, rather than continuous loss of a parent, was associated with greater depressive and other types of psychopathology in subjects who came from large families. Repeated exposure to

inescapable shock has been discussed as a model of stress-induced analgesia, 'learned helplessness', or depression (Anisman, 1984; Seligman, 1975; Drugan *et al*, 1981). The quality, intensity, periodicity, and degree of control, as well as environmental context and conditioning, which are important variables for behavioural sensitisation, also appear important to the behavioural and biochemical consequences of this stress model.

Conditioned biochemical changes

There is a growing belief in the literature that drug-induced and environmental stress-induced changes in brain biochemistry may be conditioned (Deutch *et al*, 1985; Post *et al*, 1984; Schiff *et al*, 1981; Cassens *et al*, 1981; Perez-Cruet, 1976; Anisman & Sklar, 1979; Herman *et al*, 1982). For example, Schiff *et al* (1981) have demonstrated that amphetamine-induced alterations in homovanillic acid (HVA) could be conditioned. They observed that the significant increases in mesolimbic HVA areas following amphetamine could be conditioned to a loud tone that was originally paired with amphetamine administration.

Herman *et al* (1982) have observed conditioned biochemical effects on re-exposure to stimuli previously associated with inescapable shock. Rats given inescapable shock showed increases in plasma corticosterone and brain dihydroxyphenylacetic acid (DOPAC) in frontal cortex, olfactory tubercle, nucleus accumbens, and amygdala. Re-exposure of

rats to the environment where they had been previously shocked 24 hours earlier induced elevations in plasma corticosterone and brain DOPAC in the frontal cortex only. Deutch *et al* (1985) reported parallel conditioned changes in DOPAC in prefrontal cortex and in the ventral tegmental (A 10) cell body area. Cassens *et al* (1981) also demonstrated conditioned biochemical responses in a model of learned helplessness. They demonstrated that the 3-methoxy-4-hydroxyphenylglycol (MHPG) increases, which were ordinarily elicited during the learned helplessness induction procedure, could be associated merely with the placement of the animal in that apparatus. In this regard, the selective changes in brain MHPG in animals with and without control of the environmental stress deserve particular comment.

Control over shock and environmental contingencies determines whether 'helplessness' behaviour emerges (Jackson *et al*, 1979) and the direction of the biochemical changes involved. Miller & Weiss (1969) have demonstrated increases in MHPG in the brainstem of animals subject to shock which they could terminate themselves; however, decreases in MHPG, the opposite effect, occurred in the brainstem of yoked-control animals that received, but were unable to terminate, the same shock. Vogel (1983) has recently replicated these findings measuring plasma norepinephrine, rather than brain MHPG. The behavioural effects of undemonstrable shock have also been linked to α_2 mechanisms in the locus coeruleus (Weiss & Simson, 1984) and to beta-receptor increases in the hippocampus (Henn, 1984).

FIG. 1. Schematic illustration of the longitudinal and progressive development of recurrent affective illness.

TABLE I
Parallels in the phenomenology of affective illness to kindling and sensitisation

<i>Characteristic of affective illness*</i>	<i>Characteristic of</i>	
	<i>Kindling</i>	<i>Sensitisation</i>
1. Genetic component	+	+
2. Early experience predisposes	+	+
3. Mild alterations emerge as full blown episodes (threshold effects)	+	+
4. Episodes reach plateau and are similar in content and behaviour over repeated recurrences	+	+
5. Repeated episodes of mania or depression may lead to emergence of opposite phase (conditioned compensatory reactions)	±	+
6. Onset of maximum disturbance occurs earlier in episode with repetitions	+	+
7. Vulnerability to recurrences and faster cycling	+	+
8. Early episodes may be precipitated, later appear "spontaneously"	+	
9. Lithium carbonate effective prophylaxis	-	+
10. Carbamazepine effective prophylaxis	±	-

+ = Observed; ± = Equivocal; - = Not observed.

*Numbers 1-8 also refer to those in Fig 1.

Conditioned emotional responses: possible clinical relevance

The possible contributing role of environmental events, psychosocial stress and loss in the precipitation of affective illness has been discussed extensively elsewhere (Paykel, 1979a,b; Dunner & Hall, 1980; Brown *et al*, 1975; Amelas, 1979; Lloyd, 1980). The sensitisation-conditioning suggests that symbolic components of previous triggers of a depressive response might be learned, or conditioned, such that they become capable of eliciting depression in the absence of the unconditioned stimulus; i.e. a 'real' stress or loss.

We are postulating that anticipated stresses or imagined losses, if sufficiently conditioned, may eventually be capable of producing the behavioural, physiological and biochemical alterations usually associated with an affective episode. Should this concept prove to be valid, it might provide a transitional bridge between psychoanalytical concepts of the aetiological role for real or symbolic losses, and biological-endogenous views of depression.

The kindling and sensitisation models for the way in which repetition of early loss experiences might produce overt psychopathology are schematised in Figure 1 and described in Table I. Both biological and social components could occur separately, but

our framework also considers how stress- or loss-induced reactions could evolve over time, become increasingly facilitated and autonomous, and eventually show a pattern of spontaneity. Both 'reactive' and 'endogenous' (spontaneous) episodes could occur at different times in the same patient. The model might also be relevant when repeated endogenous or exogenous events, such as repeated episodes of premenstrual dysphoria or drug-induced mania, could lead to a sensitized substrate that might then be triggered more easily by subsequent biological or psychosocial stressors. Thus, the biological and psychosocial approaches might not be mutually exclusive, but potentially interactive. This model is consistent with the data of Paykel (1979a), which show that a clear separation of reactive and endogenous depression is often not possible, even after a careful history of stress and life events.

A testable derivative of our schema would be that more clear identification of psychosocial precipitants would be possible earlier, rather than later, in the course of recurrent affective illness. Support for this concept is found in the observations of Amelas (1979), who noted that a high percentage of first manic episodes were preceded by stress. A corollary proposition would be that symbolic losses might be sufficient to trigger affective episodes later in the course of illness.

Mechanisms inherent in conditioning may also offer a conceptual approach to the emergence of apparently opposite behavioural states of depression and mania following similar precipitants (Dunner & Hall, 1980; Amelas, 1979; Cohen *et al.*, 1954; Aleksandrowicz, 1980). Siegel (1979) has reviewed the evidence that behavioural, physiological and biochemical responses opposite to those initially induced might at times appear during conditioning; i.e. conditioned compensatory responses. For example, he suggested that "subjects with a history of morphine administration display morphine compensatory conditioned responses when confronted with the usual administration procedure, but without the drug". We suggest that opposite mood responses could also develop as conditioned compensatory responses following repeated episodes of affective illness. Analogous to Siegel's formulation, we suggest that subjects with a history of depressive responses may display depression-compensatory responses (i.e. mania) when confronted with cues that would ordinarily elicit a depressive reaction, but when the timing, context, or biological substrate is altered.

Within the psychoanalytic framework, theorists have postulated that manic responses may emerge as a defence against depression (Cohen *et al.*, 1954; Aleksandrowicz, 1980; Freud, 1917). Our formulation extends this analytic framework to include the possibility that psychologically- and biologically-triggered compensatory mechanisms may also be involved in this process. Thus, we suggest that the repeated experience of depressive episodes might progressively bring into play biological compensatory mechanisms that not only help terminate the episode, but result in a compensatory manic episode. This process could provide a framework for considering a mechanism by which a large group of apparent unipolar depressed patients experience multiple recurrent depressive episodes prior to the emergence of their first manic episode (Angst & Grof, 1976). In patients with manias at the onset of their illness, compensatory processes might similarly lead to the development of depressive episodes.

One of the primary characteristics of the conditioned response is that, with time, the behavioural response begins to occur earlier in the interval and may even anticipate the conditioned stimulus (Siegel, 1979; Dollard & Miller, 1950). These findings are consistent with the more rapid onset of motor hyperactivity in behavioural sensitisation (Martres *et al.*, 1977; Shuster *et al.*, 1977; Segal & Mandell, 1974; Kilbey & Ellinwood, 1977) and the observation of the more rapid onset of manic episodes in patients with increased numbers of prior

episodes (Post *et al.*, 1981a). With sufficient repetition, compensatory responses might move progressively earlier, so that they occurred within, rather than following, an episode. Such a formulation could provide a mechanism for the evolution of dysphoric manias and activated depressions in bipolar patients. If this explanation is well founded, one predicts that these mixed states would tend to occur later in the course of a patient's affective illness after many recurrences.

Bunney (personal communication) has noted an increased incidence of mania in recovered patients in the period immediately before discharge from the hospital. It is interesting to consider that this occurs during a phase of anticipated psychosocial loss, but occurs in the absence of the unconditioned biochemical stimuli (i.e. the associated depressive substrate has been treated) and thus may be sufficient to trigger the compensatory behavioural response of mania rather than depression, just as Siegel (1979) has postulated the triggering of compensatory responses in the absence of the unconditioned stimuli during the opiate response.

The environmental context-dependency of behavioural sensitisation to cocaine and related drugs may provide another explanation for opposite behavioural effects to the same stimulus. Collins *et al.* (1979) have shown that cocaine may increase or decrease the response, depending on the associative cues. Similarly, Kopa *et al.* (1968) and Belenkov & Shalkovskaya (1980) have shown opposing behavioural responses to the same electrical stimulation of the same brain area (in the thalamus, hypothalamus or amygdala) depending on whether the animal received the stimulation when placed where it had, or had not, previously received a foot shock. Thus, it is possible that similar biochemical changes may be associated with opposing behavioural responses, depending on prior associative contexts and conditional cues.

Similarly, responsivity might be differentially affected by changes in behavioural state following pharmacological manipulations, or the endogenous changes in biochemistry that accompany affective states. Internal biological states can acquire discriminative, or cue, value and become associated with various pathological behaviours. For example, it is possible that an associative link could be established between high levels of circulating glucocorticoids and depressive affect, offering a potential explanation for early morning exacerbation of depression in conjunction with increases in glucocorticoids. The specific relationship between a pathological mood state and a given set of biological variables could thus vary depending on the

association developed through conditioning. Additionally, utilizing the concept of compensatory conditioned responses, one might suggest a mechanism for 48-h cycling. A given phase of a circadian rhythm (e.g. in glucocorticoids, classical or peptide neurotransmitters) might be associated with the switch into depression, while the occurrence of a similar change the next day might evoke the opposing manic response.

These 'theoretical vignettes' are highly condensed and are presented to stimulate discussion about possible biochemical and conditioning mechanisms underlying some clinical phenomena in affective illness. Schou (1982), Dunner and Hall (1980), and Dunner *et al* (1976) have noted that adequate lithium prophylaxis may develop gradually over a period of months in some patients. Schou does not believe this delay in onset is related to pharmacokinetic considerations or the very late onset of

biochemical changes, but to psychological processes in the patient and his family. Based on the conditioning principles discussed above, an alternative formulation could be offered. Time may be required to decondition recurrent or cyclic affective disturbances. Only after repeated experiences of psychological or biological changes, which would previously have been associated with an affective episode, but which now occur in the new substrate of lithium-induced biochemical alterations (i.e. in the absence of the unconditioned stimulus), do affective recurrences begin to subside.

Potential implications for pharmacological and psychotherapeutic treatments

The conditioning and sensitisation models described above would appear to have implications not only for possible mechanisms of action of psychotropic

FIG. 2. Pharmacology of kindling as a function of stimulus type and stage of development.

FIG. 3. Hypothetical psychopharmacotherapy of affective illness as a function of type and stage of development.

drugs and psychotherapeutic techniques, but also for suggesting alternative interventions. As reviewed in detail elsewhere (Bunney & Garland, 1984), lithium appears to inhibit a variety of acute and compensatory biochemical and behavioural changes observed following perturbations, particularly of the catecholamine system.

It is possible that other agents, such as carbamazepine, may affect other mechanisms and thus be associated with a different spectrum of clinical efficacy. Carbamazepine appears to be an effective treatment for many lithium-non-responsive, rapidly-cycling patients, both acutely and prophylactically (Post *et al*, 1984, 1985). The kindling and sensitisation models were influential in our initiating clinical trials of this anticonvulsant in affective illness. Carbamazepine inhibits amygdala-kindled seizures (Albright & Burnham, 1980; Wada *et al*, 1976; Babington, 1977), but not cocaine-induced behavioural sensitisation phenomena (Post *et al*, 1984). In

contrast, lithium appears to inhibit behavioural sensitisation, but not amygdala kindling.

As summarised in Figure 2, different stages of kindling and different types of kindling are differentially responsive to anticonvulsant treatment. For example, diazepam blocks the development of kindling, is effective in blocking completed seizures, but is ineffective for spontaneous seizures that develop very late in the kindling process (Pinel, 1983). In contrast, phenytoin is largely ineffective in the first phases, but blocks spontaneous seizures. Carbamazepine does not block the development of electrical kindling, but blocks completed amygdala-kindled seizures (Weiss *et al*, 1986a). In contrast, carbamazepine blocks the development of lidocaine-kindled seizures, but fails to inhibit completed lidocaine seizures (Weiss *et al*, 1986b). Thus, different developmental stages of an apparently unitary phenomenon such as kindling are differentially responsive to treatment.

We suggest that a parallel phenomenon might occur in affective illness, where treatment efficacy may vary as a function of course of illness. As depicted in Figure 3, psychotherapy and benzodiazepine may be effective in early stress-related dysphorias, while traditional antidepressants are effective in recurrent depression, but may exacerbate cycling in some bipolar patients. Lithium appears to be less effective in the treatment of rapidly or continuously cycling patients (Kukopulos *et al*, 1980; Prien, 1984), while these factors may be associated with better response to carbamazepine (Post *et al*, 1985, 1986; Kishimoto & Okuma, 1985). While investigators and clinicians would no doubt argue about the precise categorisations in Figure 3, and the validity of their current supporting evidence, we present the figure in order to raise the question of a differential pharmacology based on the course of illness and to stimulate further research. If valid, this concept might also suggest that underlying neurobiological mechanisms differ as a function of course of illness. Finally, the sensitisation and kindling models would predict that sufficiently early and adequate prophylactic treatment of affective illness should retard the development of later stages of the illness, such as more rapid recurrence and continuous cycling.

Dollard and Miller (1950), in their classic work, 'translated' a variety of psychotherapeutic techniques into the language of learning and conditioning. We have tried to emphasise how the sensitisation and conditioning perspectives might provide additional alternative conceptions of the impact of psychosocial stresses and psychotherapy, not only on psychological conditioning, but on biochemistry and physiology as well. Many current psychotherapeutic techniques could be viewed in relationship to providing effective cognitive restructuring (Beck, 1970: 1976), social support (Weissman, 1979), and potential desensitisation (Wolpe, 1973) or extinction of core conflicts and stress-loss precipitated reactions.

In addition, one might conceive of therapeutic strategies more systematically directed at desensitisation of critical cognitive structures, and symbolic representations of loss or stress, which have acquired cue or precipitant potential in relation to affective illness. We have found that longitudinal charting of affective episodes (Squillace *et al*, 1984; Roy-Byrne *et al*, 1985) is useful, not only in accurately describing the course of affective illness, but

also in helping to more systematically identify critical psychosocial stresses and areas of sensitivity in a given patient, which appear to be temporally related to repeated episodes of affective illness. Work in psychotherapy might also include the construction of a hierarchy of events and ideas that are particularly prone to evoke dysphoric feelings, affects, and the depressive syndrome. These might provide the focus for psychotherapeutic working through and systematic desensitisation. Particularly in patients who have achieved a relatively high state of conditioned emotional reactivity or stress sensitisation, more formal deconditioning techniques might be explored as adjunctive procedures to psychotherapy and pharmacotherapy.

A further utility of the sensitisation-conditioning model might be in the better understanding by the patient of the possible role of both psychological and biological processes in the evolution and/or treatment of his or her illness. With the increasing potential for polarisation of theory and therapy into either biological or psychosocial schools, the patient may be at a loss to understand how psychotherapy and psychosocial influences may be related to the growing evidence for biochemical abnormalities and responses to drug treatment in affective illness. The current exposition highlights the possibility that both psychological and biochemical responses can be associated with conditioning processes, which are themselves amenable to both psychological and pharmacological intervention. This frame of reference adds the longitudinal perspective to the multifactorial considerations of Akiskal and McKinney (1975) and others (Meyersburg & Post, 1979) who have emphasised biological and psychosocial interplay in the development of affective symptomatology.

The kindling and sensitisation paradigms may help focus theoretical and practical clinical attention on the longitudinal course of behavioural and biological change in affective illness, in contrast to the more frequently considered acute characteristics and treatment. We suggest these models not as accurate homologies for the depressive and manic-depressive illness, but as potentially useful constructs in the consideration of a variety of normal and pathological adaptive processes (both tolerance and sensitisation) which may occur upon the repeated presentation of physiological, biochemical or psychosocial stresses.

Alterations in Cerebral Laterality during Acute Psychotic Illness

BRUCE E. WEXLER

A new dichotic listening test (fused rhymed words) was used to monitor changes in perceptual asymmetry (PA) in patients recovering from acute psychotic episodes; some were also given a dichotic nonsense syllables test, a dichotic tone test, and a single visual field dot localisation test. Contrary to expectation, PA on the word test decreased with recovery, while asymmetry on the tone and dot tests did not change; results cut across diagnosis, could not be related to medication, and were independent of changes in overall performance. More specific hypotheses are needed than those of generalised single hemisphere dysfunction in major psychiatric illness, but existing models and concepts are inadequate to explain the findings.

Numerous studies have examined putative indices of regional brain function (RBF) in psychotic illness, including perceptual asymmetry (PA), spontaneous and evoked electrical activity, and blood flow and metabolism (Flor-Henry, 1979; Gruzelier, 1981; Merrin, 1981, 1982; Newlin, 1981; Riederer, 1981; Wexler, 1980). Most purport to have found evidence of a single localised dysfunction, and suggest that this is characteristically associated with a particular clinical disorder.

However, many have been marked by the methodological shortcomings generally found in first-generation studies: measures of RBF have often been of limited reliability and/or validity; most studies have included patients of only one diagnostic group, making it necessary when attempting to compare different clinical disorders to compare data from different studies using different experimental measures and designs; and many have only compared patients and healthy controls, without assessment of severity of illness or sick/well repeated measures. (Such procedures are essential in differentiating state from trait abnormalities, and are potentially useful in further validating and defining the nature of an association between alteration in RBF and a clinical disorder). Finally, most studies have used only one measure of RBF. Problems resulting from the use of single measures are twofold: the degrees of freedom in drawing inferences from them about possible brain dysfunction are so great that specific conclusions cannot be drawn with any confidence; and the use of single measures biases conclusions toward single localised dysfunctions, since it is then impossible to see enough to assess integrative and interactive aspects of brain physiology (Wexler, 1986).

A new and improved language-related dichotic listening test was used here to assess RBF in acutely psychotic depressed and schizophrenic patients. Subjects were presented with dichotic pairs of single-syllable rhymed words, differing only in the initial consonant. Members of each pair fuse into a single auditory image, and subjects experience and report only one word on each trial. In a multi-centre study of right- and left-handed controls, this test proved to be very reliable and to approximate the validity criteria derived from neurological patients (70% right ear advantages (REA) in sinistrals and 95% in dextrals) as closely as any test currently available (Wexler & Halwes, 1983). Although developed specifically for this study, it is now being used world-wide.

The dichotic word test was used to follow-up an earlier finding of an increase in REA on a dichotic nonsense syllable test, as depressed and schizophrenic patients recovered from acute psychotic episodes (Wexler & Heninger, 1979). The nonsense syllable test was also a fused single response test, in which members of each pair differed in only one consonant and in which the set of such consonants was the same as those distinguishing the rhymed words. To facilitate comparison of the two studies, a sub-set of subjects in the present one also received the nonsense syllables test; sub-sets of patients also received two other PA measures. The four tests together constituted the current state of development of a multi-test battery. The first of these was a dichotic tones test, in which subjects receive a different tone in each ear and indicate which sounds louder; normal subjects show a highly reliable right ear bias (Wexler & Halwes, 1981). The last test was a visual dot localisation test, modelled on one of Levy

& Reid (1978). Dots are flashed briefly in either the right or left visual field, and subjects are required to indicate the position on a response key. Normal subjects typically have a left visual field advantage (LVFA), presumably because specialised final processing of these stimuli takes place in the right hemisphere. All tests were given to subjects twice—shortly after admission, when acutely symptomatic, and again after treatment and major improvement in symptoms; severity of symptoms was assessed at both times with a multidimensional nurses' rating scale (Heninger *et al.*, 1970).

The recovery-associated increase in REA on the nonsense test, noted earlier, was hypothesised to reflect a breakdown in normal interhemisphere inhibitory processes during acute psychosis (Wexler & Heninger, 1979). The present project was designed to replicate the initial finding, and to determine whether results with other measures of PA were consistent with this hypothesis. It was predicted that because of the similarity between the word and nonsense tests, results from them should be comparable. The tone and dot tests, on the other hand, were different enough from the other two for their results to help define the limits of the pathological process reflected in them.

Method

Subjects

Patients admitted consecutively to the Connecticut Mental Health Center, who met research criteria for the diagnosis of schizophrenia or primary major depressive disorder (Spitzer *et al.*, 1975), and were right-handed, participated in the study. One patient's test scores were markedly different from all the others', and he was excluded on this basis. The median age of the remaining 26 was 40 years, range of 19–64, 11 were men and 15 women. Seven were diagnosed as schizophrenic (four men, three women, median age 25 years, range 19–38) and 19 as primary major depressives (seven men, 12 women, median age 50 years, range 23–64). All 26 took the dichotic words test. Sub-sets of 15 took the dichotic nonsense test (three schizophrenic, and 12 major depressive disorder), 19 took the dichotic tones test (three schizophrenic and 16 major depressive disorder) and 16 took the visual dot localisation test (three schizophrenic and 13 major depressive disorder). All patients were without major illness other than their psychiatric disorders and none were taking non-psychiatric medications; none had any history of neurological illness or injury, language or learning disability, or excessive alcohol or drug use.

Control subjects were right-handed and without history of psychiatric, neurological or major medical illness, learning or language difficulties, or excessive drug or alcohol use. None were taking medication with CNS effects. There were 47 controls for the words test (23 men, 24 women, median age 27 years, range 17–56); 31 for the nonsense test (nine

men, 22 women; median age 27 years, range 20–38); 16 for the tones test (eight men, eight women; median age 27 years, range 20–35); and 29 for the dot test (14 men, 15 women, median age 28 years, range 20–56).

Research design

Patients were tested initially seven to 14 days after admission, when actively symptomatic. Each PA test was given twice on the same day, and the results combined. Word and nonsense tests were given on separate days, with about half the subjects receiving the word test first and the other half receiving the nonsense test first. The dot and tone tests were often given on the same day, with a two hour break between tests, and were generally given after the word and nonsense tests. All tests given initially were then repeated 12 to 145 days later (median 50), when clinical staff considered that maximum expected clinical improvement had occurred. Fourteen patients were off all medication at the time of initial testing (median in hospital drug-free period was ten days, range seven to 14), eight of the remaining 12 were on the same or the same class of medication (e.g. antidepressant) on initial testing as they were on retesting. The remaining four patients discontinued or had a change in class of medication between the initial and final testing. The depressed patients were treated with TCAs and/or lithium carbonate, all within usual therapeutic dose-ranges. The schizophrenics were treated with haloperidol or chlorpromazine, within usual dose-ranges. All 23 controls for the nonsense test took the test repeatedly, 11 with a nine-week inter-test interval, and the remaining 12 with less than a one-week interval; 18 word test controls, all 16 tone test controls, and ten dot test controls were retested within one week of original testing.

Behavioural measures

Once during the 7 am–3 pm shift and once during the 3–11 pm shift, patients were rated by nursing staff on a 13-item clinical rating scale, identical to one described by Heninger *et al.* (1970), save for the elimination of an expressed anger rating. Ratings on the day prior to a PA test, the day of the test, and the day after the test (six ratings in all) were averaged for a clinical rating to correspond to each PA value.

Perceptual asymmetry tests

The dichotic word, nonsense, and tone tests have all been described elsewhere (Wexler & Halwes, 1981, 1983; Wexler & Heninger, 1979). The word test consists of 15 different single syllable word pairs, in which each member of every pair differs from the other only in the initial consonant, e.g. coat, goat. All words begin with one of six stop consonants, b, d, p, t, g, k, and are natural speech, spoken by a male voice. The initial consonant portion of one member of each pair was cross-spliced onto the vowel-final consonant portion of the other member on the DDP 224

Computer System at Haskins Laboratories. The members of each pair fuse into a single auditory image. Consequently, subjects are aware of hearing, and report only one word on each trial. Each pair is presented twice in 30 trial blocks, the second time with each word to the ear opposite that of the first presentation. Four such 30-item blocks make up the test, for a total of 120 trials. Subjects indicate what word they heard by making a line through it on an answer sheet that has four possible responses—both members of the dichotic pair and two other words differing from the dichotic stimuli only in the initial consonant. A score for each ear is determined by totalling the number of times the word presented to that ear is the one indicated: an error is scored when neither of the pair is chosen.

The nonsense test consists of dichotic pairs, made up of the six stop consonants, b, d, p, g, t, k, preceded and followed by the vowel 'a' (e.g. aba, aka). The stimuli are synthetic copies of natural speech. As in the word test, the members of each pair fuse into a single auditory image, and subjects expect, experience, and report only one response on each trial. Three of the 15 possible pairings of the six syllables were found to be subject to frequent phonemic blending errors (Halwes, 1969) and were therefore discarded. The remaining 12 pairs were presented twice in 24-pair sequences, the second time with each syllable to the ear opposite that of the first presentation. Four such blocks were combined to make a 96-trial test. Subjects indicate what syllable they hear by writing b, d, p, g, t, or k in a blank space between two a's on a prepared answer sheet. The test is scored as for the word test.

In the tone test, each dichotic pair consists of a 440 and a 450 Hz tone, differing in volume by 0–10 dB; subjects indicate which sounds louder. If subjects indicate that one ear signal was louder when in fact the opposite was true, the ear chosen is assigned a number of points equal to the number of decibels by which the stimuli differed in intensity. Right- and left-ear scores are combined to give a total error score. All test tapes were made at Haskins Laboratories in collaboration with Terry Halwes. Tapes were played on a Teac-2-track master recorder, and stimuli delivered through matched pairs of TDH-39 earphones. Calibration tones at the beginning of each tape were balanced to minimise channel effects, while remaining channel effects were controlled by reversing earphones after the first and third quarters of the tests. In all tests, subjects received practice trials before the start, to familiarise them with the procedure and to decrease anxiety and errors. On the words and nonsense tests, subjects were not told, and did not realise that they were getting different inputs in each ear on each trial. In the loudness test, they were told they would hear a different tone in each ear, and should indicate which sounds louder.

The visual dot localisation test was modelled after one developed by Levy & Reid (1978). Subjects are instructed that a single dot will appear in one of 40 possible positions within a circular frame, encompassing both the left and right fields; there are 20 different, randomly chosen positions, mirrored in the two visual fields. Stimulus slides are exposed for 120 msec. Subjects report the location of the dot from a hand-held response key. The circular frame extends to 3.5° lateral of fixation, with dot positions

ranging from 0.7° to 2.7°. Subjects sit 30 inches from the screen, directly in front of the central fixation point.

A digit, 0–19 is presented in the centre of the field on each trial and subjects report this digit before indicating dot location; this central digit subtends an angle of 0.2°. The pre-stimulus fixation/post stimulus noise slides consist of an x in the centre for fixation, and several different types of visual noise in the remainder of the slide. Dots are presented once in every position in each visual field for a total of 40 trials, with a two-minute rest after 20 trials. Trials on which the central fixation number is incorrectly reported are not scored, and are repeated at the end.

The numbers of items correctly identified in each field constitutes the score for each; the numbers of items identified incorrectly in both, together constitute a total error score. Results from subjects who made more than 75% errors were discarded. Prior to the test, subjects were familiarised with the procedure and stimuli by being shown similar slides, and were required to identify the central number and to indicate whether or not a dot was present.

Auditory acuity was tested in each ear by the method of ascending and descending limits, using tones of 250, 500, 1,000, 2,000, and 4,000 cps; no subject had a difference in auditory acuity between the ears of more than 5 db on more than two of the five frequencies tested. Handedness was assessed by observing which hand was used in each of eight tasks: writing, throwing a ball, dealing cards, opening a jar, threading a needle, brushing teeth, cutting with scissors, and striking a match. All subjects wrote and did at least five of the other seven tasks with the right hand.

Data analysis

Laterality scores were calculated by subtracting left-ear (or visual field) scores from right-ear (or visual field) scores, and dividing the difference by the sum of the two. Independent t-tests were used to evaluate mean differences between groups, paired t-tests to evaluate change within subjects over time, and Pearson correlation coefficients to evaluate relationships among the variables.

Results

Patients compared to controls

On the dichotic nonsense and tone tests and on the visual dot test patients, when first tested, tended to be less lateralised than controls, but none of these differences reached the $P < 0.05$ level of statistical significance. Mean laterality for the patients on the nonsense test was 0.03 ± 0.19 , for the controls 0.12 ± 0.18 , 2 tail $P < 0.10$, on the tone test 0.07 ± 0.59 and 0.33 ± 0.45 , $P < 0.17$, and on the dot test 0.03 ± 0.17 and -0.08 ± 0.21 , $P < 0.09$. Asymmetry on the word test among patients when they were acutely symptomatic was essentially identical to that among controls; 0.13 ± 0.14 and 0.13 ± 0.15 . Patients made more errors than controls did on the word test (pts. 5.4 ± 4.76 , con. 1.8 ± 2.1 , $P < 0.001$) and on the nonsense test (pts. 2.5 ± 3.1 , con. 0.38 ± 1.1 , $P < 0.05$), but patients and control error rates were not significantly different on either the

TABLE I

Changes in dichotic nonsense and dichotic words tests with recovery from acute psychotic episodes

<i>Nonsense (n=15)</i>	<i>Sick</i>	<i>Well</i>	<i>P value (2-tail)</i>
Laterality (PD index)	0.03 ± 0.19	0.07 ± 0.20	P=0.10
Errors	2.8 ± 3.2	5.1 ± 7.1	P=0.13
Word Test (n=26)	Sick	Well	P value (2-tail)
Laterality (PD index)	0.13 ± 0.14	0.06 ± 0.11	P=0.001
Errors	5.4 ± 4.6	4.1 ± 5.1	P=0.28

tone or the dot test. There were no significant correlations between error rate and asymmetry on any of the tests in either controls or patients. Results of each statistical comparison were essentially the same when sub-groups of the sample (depressives, schizophrenics, patients off and on medication) were examined separately.

Changes in asymmetry with clinical improvement (Table I)

Following treatment and clinical improvement there was a decrease in PA on the dichotic word test; initial mean laterality 0.13 ± 0.14 , retest 0.06 ± 0.11 , 2 tail $P < 0.001$. The sub-set of 15 patients who also took the nonsense test showed the same increase in laterality noted in an earlier study; laterality means 0.03 ± 0.19 and 0.07 ± 0.20 , one tail $P < 0.05$. Changes in the tone test (0.07 ± 0.59 and 0.02 ± 0.06) and in the dot test (0.03 ± 0.17 and 0.02 ± 0.14) did not approach significance. The degree of change in PA in individual patients on the nonsense test was not correlated with the degree of change on the word test (Pearson correlation 0.08). Changes in all tests were similar in sub-groups defined by diagnosis (schizophrenia or depression) or by medication status (group 1 off medication initial testing, on antidepressant medication second testing, group 2 on the same medication for both initial and repeat testing). Controls did not show significant changes with retesting on any of the four tests. Error rates on neither the word test nor the nonsense test changed significantly with clinical improvement.

When recovered, asymmetry on the word test in the patient group was significantly less than in the controls (pts 0.06 ± 0.11 , controls 0.14 ± 0.16 $P < 0.04$). Asymmetry on the nonsense test, which had been less than that of controls when patients were sick ($P < 0.10$), moved closer to control values (pts. 0.07 ± 0.20 , controls 0.13 ± 0.18 , $P < 0.26$). Asymmetry on both the tone and the dot tests moved farther from control values with recovery so that differences between recovered patients and controls were significant on both tests (tone test, pts 0.02 ± 0.47 , controls 0.33 ± 0.45 $P < 0.03$; dot test pts. 0.04 ± 0.4 , controls -0.08 ± 0.21 , $P < 0.05$).

Correlation between PA and clinical symptomatology

Two sets of correlations between PA and symptomatology were calculated; between initial PA scores and initial clinical ratings, and between recovery-related changes in PA and degree of symptom improvement. The correlations between PA on the tone and dot tests and clinical ratings were not significant in either of the sets with a frequency greater than would be expected by chance alone. The same was true for initial PA scores on the word and nonsense tests and initial nurses' ratings. Errors on the word test when patients were acutely symptomatic were positively correlated with ratings of odd or unusual thoughts (0.58 $P < 0.002$), anxiety (0.40 $P < 0.04$), disorganised thinking (0.53 $P < 0.006$), hallucinations (0.47 $P < 0.01$), paranoia (0.44 $P < 0.02$) and overall psychosis (0.57 $P < 0.002$). Correlations between errors on the nonsense, dot and tone tests, and clinical ratings were not statistically significant.

The correlations between recovery-related changes in PA and errors on the word and nonsense tests, and recovery-related changes in nurses' ratings are presented in Table II. All change variables were calculated by subtracting initial values from time two values (repeat or well values). Thus, an increase in laterality on the nonsense test would lead to a positive change score, while a decrease in laterality on the word test, a decrease in test errors, or a decrease in symptomatology would lead to a negative change score. Correlations between changes in PA on the nonsense test and changes in severity of symptoms were consistent with the recovery-related increase in laterality in group mean scores. Those patients with larger increases in laterality on the nonsense test had greater improvement in ratings of odd and unusual thoughts, disorganised thinking, hallucinations, paranoia, and overall psychosis. Neither changes in the overall depression rating nor in specific aspects of depression (ie. anxiety, withdrawal, agitation, motor retardation, decreased energy) were correlated with changes in asymmetry. In contrast, on the word test, only changes in the magnitude of social withdrawal, motor retardation and decreased energy—all symptoms associated with depression—were significantly correlated with change in PA. However, the direction of correlation was opposite what might be expected from the group mean decrease in asymmetry on the word test with recovery: those patients with smaller decreases in laterality exhibited greater improvements in symptomatology.

Decrease in errors on the words test was positively correlated with improvement in ratings of psychotic symptomatology. Although change in laterality on the nonsense test was also correlated with change in most of the same symptoms as was change in words test errors, the correlation between change in laterality on the nonsense test and change in overall errors on the words test was not significant (0.23). The extent of change in errors on the other PA measures were not correlated with change in ratings of symptoms.

Separate analyses were conducted for patients off medication when ill, patients on medication both ill and well, schizophrenic patients, and depressed patients. In patients off medication, PA on the word and nonsense tests when ill tended to be more highly correlated with ratings of

symptoms than they were in the entire group, but patterns of correlation in other groups were similar to those of the entire sample.

Discussion

The recovery-related increase in PA on a dichotic nonsense test, noted by Wexler and Heninger (1979), was replicated here; in that study, the degree of increase in asymmetry on this nonsense test was correlated with the degree of decrease in clinical ratings of paranoia, and this correlation was confirmed. In addition, the degree of increase in asymmetry was found to correlate with the degree of improvement in ratings of odd and unusual thoughts, disorganised thinking, hallucinations, and overall psychosis. When ill, patients showed less asymmetry than healthy controls; the increase in asymmetry with recovery moved patients' asymmetry values closer to those of controls'.

Perceptual asymmetry on a dichotic word test decreased as patients recovered. Despite the fact that this test was very similar in task, structure, and stimulus characteristics to the nonsense test, the recovery-related change in PA on this test was opposite in direction to that on the nonsense test. Recovery-related changes moved patients' asymmetry away from control values, so that although patients' group mean asymmetry was essentially identical to that of controls when the patients were ill, when they recovered, their mean asymmetry was significantly less. Those patients with the greatest decreases in PA with recovery tended to show the smallest decrease in ratings of social withdrawal, motor retardation, and decreased energy—which can be related to depression and/or side-effects of medication. The decrease in PA on the word test was not related to the change in ratings of psychosis or of psychotic thought processes.

Errors on the dichotic word test were positively correlated with ratings of psychotic thought and behaviour when patients were ill, while recovery-related decreases in errors were positively correlated with improvement in these ratings. The relationships between errors on the word test and the clinical variables were very different from those between errors on the other tests and these variables. When ill, patients made significantly more errors than controls on the word and nonsense tests, but not on the dot or tone tests; it was only on the word test that errors were significantly correlated with clinical variables. In controls, the word test consistently yielded fewer errors than any of the others. Together, these observations suggest that the associations between errors on the word test and clinical

variables reflect a specific aspect of brain dysfunction, and are not merely a reflection of the general decrement in performance associated with psychosis.

Data generated by the tone and dot tests were not robust: group mean values on neither test changed significantly as patients recovered, and neither asymmetry nor errors on either test correlated significantly with clinical ratings. However, when ill, patients tended to be less lateralised on both tests than were controls. With recovery, patients' values moved further from those of controls, and the differences became statistically significant.

Interpretation of these data is difficult: firstly, because recovery-related changes on different tests are in different directions, both with respect to initial illness values and controls, and secondly, because there are data from four different tests. It would be easier to consider those from only one or two, but such simplification would merely cause delay. Despite such efforts, however, an interpretation that incorporates all statistically significant findings has not so far been possible, but as the addition of new pieces to a complex puzzle provides places for those previously impossible to fit, future studies will perhaps allow interpretation of all current data.

Recovery-related changes in asymmetry

It is striking that asymmetry on two tests as similar as the dichotic word and nonsense tests would change in opposite directions with recovery. The fact that the change on the nonsense test has been replicated, together with the high statistical significance of change in the word test, suggests that the difference in direction is worthy of attention. There is also support from three other sources. Firstly, similar opposite changes in asymmetry on these same two tests have been noted in healthy subjects with administration of concurrent visual tasks (Wexler & Halwes, 1985). Secondly, the two tests fluctuate in opposite directions from day to day in depressed patients during the initial phase of ECT (Wexler *et al.*, unpublished). Lastly, schizophrenics have greater asymmetry than controls on a dichotic word test (Lishman *et al.*, 1978), and less on a dichotic nonsense test (Colburn & Lishman, 1979).

It seems unlikely that the differences between the word and nonsense tests result from merely procedural factors. In the previous recovery study, the nonsense test was given alone, and the same increase in PA with recovery noted; the nonsense test was given on successive days, as were the word and nonsense tests in the present study, and scores on each of the illness test days were lower than those on the well days. To control for test-order effects, in the present study, half the patients who received both

tests received the word test first, and half the nonsense test first: those who did not take the nonsense test showed the same decrease in PA as did the entire group. Finally, an unpublished study found inter-correlations ranging from 0.52 to 0.70 ($n=40$, $P<0.001$) among four word tests, each modelled after the one used in this study but differing in the emotional quality of stimulus words. Together with the high test-retest reliability of the word and nonsense tests, this makes it unlikely that the differences observed here between them are due to the administration of multiple tests.

Explanation of the results must be *post hoc*, since they were unanticipated, and requires validation. Three explanatory approaches were considered: that changes on the two tests represent different and independent regional brain dysfunctions; that dysfunction of a single brain region, anatomically defined, accounts for changes in both tests; and that a single change in brain physiology accounts for changes in both tests. The first, though supported by the absence of correlation between recovery-related changes in PA on the two tests, was rejected: each of the possible independent dysfunctions must differentiate between word and nonsense stimuli, altering one test but not the other. In addition, unless the number of such hypothetical functions and dysfunctions is to be increased, the same two functional alterations must be postulated to account for the changes in asymmetry seen in healthy subjects with concurrent visual tasks (Wexler & Halwes, 1985), and for the reciprocal day-to-day changes in asymmetry on these tests, noted in depressed patients during the initial phase of ECT (Wexler *et al.*, unpublished).

The second possibility—that dysfunction of a single anatomically defined area led to opposite changes in asymmetry—seems improbable. According to existing models of perceptual asymmetry, change in function of all areas that contribute to asymmetry on both tests would affect both tests in the same way. It is possible, however, that efficiency of information processing in a particular area varies along an inverted U-shaped curve as a function of activation (or other factors) of that area, and that because of differences in the functional demands posed by processing words and nonsense, these two processes are at times on opposite sides of the maximum point of this curve. Changes in the function of such an area with disease, concurrent visual tasks, or ECT could then have opposite effects on asymmetry on the two tests. Dysfunction of a single anatomical area then remains a viable explanation, and one that might be amenable to further experimental validation.

The third approach invoked the possibility that a single physiological alteration might account for the opposite changes on the words and nonsense tests. I have developed (Wexler, 1986) a physiological model of brain function, based on Luria's notion of cerebral functional systems: specific behaviours or cognitive functions are not localised in specific brain regions, but are the result of the concerted action of a functional system. The specific anatomical components of these systems may vary, while the behavioural or cognitive output remains constant, and from this perspective, integrative and interactive processes within and among functional systems are central in normal brain function. Major alterations in mood and behaviour would be associated with changes in these processes.

The simultaneous and unacknowledged presentation of different stimuli to each ear in dichotic tests create unnatural functional demands: perceptual asymmetry is not an index of ordinary function. It probably does not make sense, therefore, to speak of the functional systems for processing the dichotic word and nonsense stimuli. The present data suggest, however, that in recovery from acute psychotic states the functional systems for processing auditory information as meaningful or as nonsense are altered in such a way as to have opposite effects on PA in the dichotic words and nonsense tests. A unitary explanatory hypothesis suggests that there is a change in the relationship between the functional systems, leading to opposite changes in PA.

The degree of PA is thought to reflect, among other things, facilitation of information flow from the right ear by stimulus-specific activation of left hemisphere attention centres (Kinsbourne, 1975). Assuming that the degree of such activation is proportional to the activity of the stimulating functional system, the present data suggest that: (1) the functional system for processing auditory information as meaningful, and that for processing auditory information as nonsense, are normally in a mutually inhibitory relationship, and (2) in some cases of acute psychosis, the balance of activity of the two systems is altered so that the functional system for processing auditory information as meaningful is more active and that for processing information as nonsense is less active. Decreased activity of the functional system for processing auditory nonsense during acute illness would lead to decreased activation of left-hemisphere attention centres and, consequently, less facilitation of the right-ear input pathway and a decreased right-ear advantage with presentation of nonsense stimuli. A similar decrease in activity of the functional system for processing auditory words with recovery would

lead to the recovery-related decrease in asymmetry seen on that test.

The increase in errors on the word test, seen on initial testing, suggests that with a shift in the reciprocal balance between the word and nonsense systems toward the word system in acute illness, efficiency of the word system decreases.

Correlations between specific symptoms and laterality variables

Increase in PA on the nonsense test was significantly correlated with decrease in symptoms of psychotic thinking, but not with change in symptoms in energy level, or in motor or social activity. It is interesting that this was so in a group who were mainly psychotically depressed. The nature and extent of cognitive disturbance found in major depressive illness are variable, and these data suggest that PA on the nonsense test is associated with this important but variable component of the syndrome. Change in PA on the words test was not correlated with change in these symptoms, but instead tended to show an inverse correlation with change in social withdrawal, motor retardation, and lack of energy; those individuals with the greatest improvement in the symptoms showed less of the recovery-related decrease in PA that characterised the group as a whole. This is of interest because of the direction of the association, which suggests that a recovery and/or treatment-related change in brain function, as reflected in PA on the words test, may have a negative effect on certain symptoms. Identification of this process might aid in the improvement of treatment.

Errors on the word test when patients were ill were positively correlated with the severity of symptoms of psychotic thinking, and the degree of decrease in errors with recovery was correlated with the degree of improvement in these same symptoms. These associations are straightforward, and consistent with the recovery-related decrease in group mean errors. However, the association of errors on the word test with symptoms different from those associated with PA on that test eludes the explanation that errors on this test result from the same process that alters PA in it.

Asymmetry on the tones and dot tests

Asymmetry on these tests did not change with recovery for the group as a whole, and was not associated with particular symptom ratings. Some individuals did show changes on one or another of the two tests, and these may prove useful in defining clinically or physiologically meaningful sub-groups.

The absence of significant group-wide changes with recovery on either of these tests indicates some limits of the pathophysiological alterations revealed in the changes on the word and nonsense tests. Earlier writers suggested that global dysfunctions of one hemisphere or the other characterised the major psychiatric disorders. The interpretation here of opposite changes in PA on the word and nonsense tests is more specific, suggesting change in the functional relationship between two functional systems, each with important components in the left hemisphere, instead of a general left-hemisphere dysfunction. The absence of recovery-related changes in the dot and tone tests is consistent with such a limited hypothesis, but not with the earlier and more general one. The differences between controls and patients on these tests, when patients are recovered, do not fit the interpretation of recovery-related changes on the word and nonsense tests, however.

Conclusion

Four PA measures, with demonstrated reliability and validity, were used here to collect a large amount of data, which proved confusing, thus demonstrating the inadequacy of existing concepts and models in describing brain function and dysfunction. It has been postulated that normally, the functional systems

for processing auditory words and nonsense are in a mutually inhibitory balance. Considerable confusion remains, however, indicating the primitive stage of the experimental and theoretical work. Though difficult, multi-dimensional physiological studies are essential if the organisational principles of the brain as an organ are to be discovered.

The most significant suggestion from the data is that normally, the functional systems for processing auditory words and nonsense respectively are in a mutually inhibitory balance. It is interesting to consider such a possibility from the perspectives of both normal and pathological development, since at first, during childhood, all is nonsense. It is also interesting to consider it in relation to those symptoms of psychosis which might be considered to reflect excessive assignment of significance—ideas of reference, delusions, and hallucinations.

Maintenance Treatment of Erectile Impotence by Cavernosal Unstriated Muscle Relaxant Injection

G. S. BRINDLEY

Intracavernosal injection of phenoxybenzamine or papaverine has been tried on 127 men suffering from erectile impotence. In 113 of them it caused an erection which should have sufficed for coitus. Seventy-three men have used such injections, given at home by themselves or their wives, fortnightly or less often, to make coitus possible after each injection; 54 of them still do so.

Virag (1982) reported that injection of papaverine (80 mg) into a corpus cavernosum caused enlargement and stiffening of the penis, and a rise in pressure in the corpora cavernosa of up to 70 mmHg, lasting 10 to 20 minutes. He described using such injections, given every two or three months, as treatment. The purpose was not to enable patients to have sexual intercourse during the artificial erections caused by papaverine, but to achieve benefits lasting from one injection to the next. Such benefits were reported by some patients.

In August 1982, before Virag's work was published but after his discovery had been made, I found in self-experimentation that phentolamine or phenoxybenzamine caused erection when injected into a corpus cavernosum. These erections lasted a few minutes for phentolamine and several hours for phenoxybenzamine. I began almost at once to use phenoxybenzamine as maintenance treatment in erectile impotence, patients learning to inject themselves in order to have sexual intercourse the same day (Brindley, 1983). I became aware of Virag's earlier work on papaverine, and of his subsequent publications (Virag *et al*, 1983, 1984) in November 1983, and began to use papaverine as an alternative to phenoxybenzamine in December 1983.

Zorgniotti & Lefleur (1985) have reported using intracavernosal injection of a mixture of papaverine and phentolamine as maintenance treatment for impotence, and Virag (1985a) is now using papaverine in this way.

The general procedure of causing erection by intracavernosal injection of a drug needs a name. The drugs that are known to swell the penis (Brindley, 1986) are phenoxybenzamine and papaverine (both of which give erections lasting for hours, usually complete), phentolamine, thymoxamine, verapamil, naftidrofuryl, lignocaine and imipramine (which give erection, complete or incomplete, lasting a few

minutes) and guanethidine (which causes shrinkage of the penis for about the first hour, and then partial erection lasting many hours). All these drugs are relaxants of unstriated muscle. I therefore call the procedure CUMRI (cavernosal unstriated muscle relaxant injection), which has the merit of being easily spoken. The name cavernosal alpha-blockade (CAB), used earlier, was appropriate for phenoxybenzamine but is inappropriate for papaverine. Virag (1985b) has recently introduced the abbreviation PIPE (pharmacologically induced prolonged erection). Theoretically this term could be much broader than CUMRI, and could include drugs given by routes other than the cavernosal. As long as no other effective route is known, however, it carries the same meaning apart from excluding the short-acting agents.

The present paper reports the use of CUMRI to investigate 127 men with erectile impotence, and to treat 73 of them.

Table I classifies them by age and principal relevant disabilities. All impotent patients to whom at least one intracavernosal injection of a drug intended to cause erection was given before 31 December 1985 are included.

Technique

Since March 1983 the following procedure has been used. For phenoxybenzamine, 0.04-0.20 ml of the concentrated solution (containing 2-10 mg of the drug) is diluted with 10 ml of saline for doses up to 5 mg, or with 20 ml of saline for doses between 5 and 10 mg. For papaverine, the solution supplied by the manufacturer is undiluted. The dose is 16-120 mg (0.4-3.0 ml).

The injection is delivered through a 16 mm needle of 0.5 mm external diameter into one corpus cavernosum in the proximal third of the free penis. The corpus cavernosum into which the drug has been injected is squeezed firmly for

TABLE I
Present state of patients

1. Spinal cord injury 36, multiple sclerosis 7, spina bifida 1, poliomyelitis 1, paraplegia of obscure origin 1.

2. Mostly with no known relevant disease, but including 3 former alcoholics, 3 men with intermittent claudication, 2 with lesions of the hypogastric plexus, 2 schizophrenics formerly treated with phenothiazines, and 8 diabetics.

3. Includes one patient who died of coronary thrombosis after using CUMRI for 27 months.

4. Includes one patient who died of carcinoma of bladder.

5. Includes one patient who died of carcinoma of the colon.

Both the carcinomas had been diagnosed before the patients received their first injections.

about two seconds along its whole length with the thumbs and fingers of both hands simultaneously, to transfer the drug to the other side. The corpus cavernosum of the other side is then squeezed in the same way. Finally, the penis is pinched transversely with one hand at six or more different places so that the drug reaches both ends of the corpora cavernosa. This massaging procedure after injection is probably important in achieving consistency of effect. Stackl & Bucher (1984), who did not use it, reported failure.

I always give the first injection myself. Some patients lie supine, as a precaution against immediate fainting, but the majority sit for the injection. From the second or third injection the patient (or in a few cases his wife) begins to learn to inject. Patients inject standing or sitting. They are allowed to take a supply of the drug home when they have demonstrated their competence, and are asked to give the injection always in the same part of the penis, so that local fibrosis can be easily detected if it occurs.

I now always try papaverine first. If it gives an adequate erection it is the better drug to use, because side-effects are rarer and the dispensing procedure simpler. If the erection from papaverine is too brief, phenoxybenzamine usually gives more prolonged erection. Before March 1983, injections were made in the middle of the free penis, and the massaging procedure was less thorough. On 10 February 1986, for reasons explained below I ceased using phenoxybenzamine except in one patient.

At present, as a precaution against long-term harm, a limit on the frequency of injections is set at once per fortnight for phenoxybenzamine, and once per fortnight on average (i.e. 26 per year) for papaverine. The reason for making different rules for the two drugs is that there is no refractoriness for papaverine, but phenoxybenzamine works less well on the second of two trials within a few days of each other.

Results

In the majority of both impotent and normal men, CUMRI with phenoxybenzamine or papaverine causes the penis to become fully or almost fully stiff, so that it can be bent to right or to left through no more than 20° (i.e. to no less than 160°). The erection is restricted to the corpora cavernosa, the glans and corpus spongiosum do not swell, or swell very little. Some men develop only poor erections if they lie down to receive the injection and remain lying down, but the erection improves if they stand.

With papaverine, the greatest degree of erection is reached within 4-8 minutes. It commonly stays constant for 1-4 hours, and then subsides completely during 1 hour or less, leaving no obvious after-effect. With phenoxybenzamine, the greatest degree of erection may not be reached until 20 or even 40 minutes after the injection, though in some men it is attained within 10 minutes. It commonly stays constant for 2-6 hours, and then subsides slowly. The penis remains large for at least 24 hours, sometimes 72 hours, and during this period of enlargement erection is often easier to provoke by psychological or mechanical stimulation than before the drug was given.

Table I shows the state of all 127 patients, as known at 1 February 1986. In 113 patients, CUMRI with papaverine or phenoxybenzamine made the penis, for a period of at least 20 minutes, continuously stiff enough to resist bending at the middle of the shaft to 135° (i.e. through 45°) to right and left. This is roughly the threshold for successful coitus. In 14 patients, not even this degree of erection was achieved by CUMRI, though in some of them a larger dose might have succeeded. Failure is significantly more common in older patients. In 40 patients, CUMRI gave a degree of erection that could have allowed coitus, but has not been used at home for this purpose.

TABLE II
Classification of present users by date of first therapeutic use of CUMRI and drug used at 1 February 1986

Total	1	6	6	9	8	16	8	54

Nineteen patients used CUMRI at home for a time, but no longer do so. One of these died suddenly after he had been using CUMRI (always phenoxybenzamine) for 27 months. Necropsy showed myocardial infarction from coronary thrombosis. He was well until a few hours before his death, and had sexual intercourse with the help of CUMRI 5 days before his death. I had palpated his penis 8 weeks before he died, and found it entirely free from lumps. He told me on that occasion that it was straight when erect.

Reasons given for ceasing to use CUMRI have included improvement, so that it was no longer necessary (3 cases); deterioration in the response to the drug (2 cases); loss of sexual partner (2 cases); and implantation of a penile prosthesis (1 case).

At 1 February 1986, 54 patients are still using CUMRI at home. Table II classifies them by drug used and length of use.

Benefits

All patients who have used CUMRI at home say that they have had coitus after every or nearly every injection, though they were always (48 patients) or usually (25 patients) incapable of intromission before treatment began. After papaverine injection, coitus is possible only in the first hour or few hours after injection. Of the 26 patients who have used phenoxybenzamine, 11 say it is often possible on the second, third, or fourth night as well.

No patient who was completely impotent when first seen has reported improvement other than the ability to have coitus in the first few hours (or for phenoxybenzamine the first four days) after an injection.

Among incompletely impotent patients, seven have reported general improvement. Three of these are now ex-users; two are non-users, having improved so much after one or three CUMRI in the clinic that they did not need to use it at home; and two are users, their improvement being insufficient to allow them to do without CUMRI.

Unwanted effects

Pain from the injection

Most patients feel a mild burning pain throughout the penis after injection of either drug. There is little difference in the severity of the pain between the two drugs, but it lasts 10-15 minutes for phenoxybenzamine and less than 2 minutes for papaverine. Accidental subcutaneous injection of phenoxybenzamine causes pain that is more severe than that from intracavernosal injection.

Haematoma

A haematoma, either subcutaneous or under Buck's fascia, appears after a small minority of injections. It is unsightly, but disappears in a few days and causes little pain or discomfort.

Injection into the urethra

A tetraparetic patient with defective penile sensation once accidentally injected papaverine into the urethra. Blood trickled from the meatus for a few minutes, but no other harm was noticed.

Priapism

The duration of action of both drugs is fairly consistent for a given dose in a given man, but it is dose-dependent, and for a given dose varies greatly between men. Priapism, defined as erection lasting continuously for at least 12 hours, has occurred in eleven patients (16 incidents). Some of these have been reported elsewhere (Brindley, 1984). Four incidents resolved spontaneously after 16-26 hours; all the other 12 were successfully treated with metaraminol. The cause was phenoxybenzamine in four incidents and papaverine in 12.

Decrease in the effectiveness of CUMRI

This has occurred in four patients: two using phenoxybenzamine, and two papaverine. In one phenoxybenzamine user the deterioration was slight, but since initially the erection produced by CUMRI was only just adequate for coitus even a slight deterioration made it inadequate, and he ceased to use the procedure. In the other phenoxybenzamine user the deterioration was severe. His erections from CUMRI with phenoxybenzamine were easily adequate for coitus on the first two fortnightly trials, not quite adequate on the third, and not at all adequate on the fourth and fifth. Six months later I did another CUMRI with phenoxybenzamine, and it again caused erection easily adequate for coitus. In the two papaverine users the deterioration was slight, and they continue to use papaverine successfully.

Non-local effects of papaverine

Two patients fainted within a minute of the injection, one of them twice. Both said they had fainted after other injections, and the faints were probably a reaction to the procedure rather than the drug. No other non-penile effects have been reported after papaverine, except for one report of trembling and sweating after 40 mg, though 80 mg had caused no trouble.

Non-local effects of phenoxybenzamine

Even as low as dose as 2 mg may make a patient aware of an increase in nasal resistance to air flow, although some patients deny it, on direct questioning, after 8 mg. Six patients have had evident postural hypotension; one fainted during a meal 3 hours after an injection of phenoxybenzamine (5 mg), one fainted at home after giving himself an accidental overdose, the exact amount being unknown; one fainted at a railway station 2.5 hours after injection (5 mg); and three patients reported minor episodes of feeling faint when standing, relieved by sitting down. The last five of these patients have continued to use the drug, at lower dosage. Three patients have reported dry orgasms, one on all of six trials and the others once each. Urinary incontinence was reported by one patient on two occasions, probably contributed to by his multiple sclerosis. Headaches, lasting several hours, were reported by one patient after each of seven doses of phenoxybenzamine (4 mg) which gave full erection for 2-4 hours. He then changed to papaverine (80 mg) which caused no headache and gave erection that was only slightly less complete and lasted long enough (1 hour). One patient had two episodes of dyspnoea, each lasting 3 minutes, during the first 12 minutes after injection of phenoxybenzamine (5.5 mg).

Local fibrosis

Repeated insertion of needles into any site might be expected to cause local fibrosis, by analogy with the fibrosis that occurs in muscles into which diabetics inject insulin. I recommend that patients always inject into the same part of the penis, to make it easy to detect fibrosis if it occurs. They are asked to feel from time to time for lumps at this

site, and I palpate the penis whenever I see a patient, i.e. at 6-monthly or (usually) shorter intervals. Patients are asked also to watch for changes in the curvature of the erect penis. No change in curvature has yet been detected in any patient, but one man, after only nine injections of papaverine, developed palpable firmness close to the injection site. He was placed on a waiting list for a penile prosthesis, and this was implanted in August 1985. The fibrosis found was very slight, and caused no difficulty in implanting the prosthesis.

Theoretical risks not yet observed*Infection*

There have been no signs or symptoms of infection after any injection.

Thrombosis

This was to be feared after prolonged priapism, but did not occur. The longest episode of priapism was 40 hours. After this, as after all other episodes, the penis returned rapidly to its normal flaccid size and flexibility. In 10 of the 11 affected patients, full erection occurred subsequently under CUMRI. One patient, who was incompletely impotent, has had no subsequent CUMRI, but he reports that his psychogenic and reflex erections, after being worsened for a few weeks by the episode, recovered and became better than before.

Oncogenesis

Phenoxybenzamine given in large doses by intraperitoneal injection to rats has been reported as causing sarcomata (Flind, 1984). It is approved by the Committee on Safety of Medicines for intravenous injection for very limited indications, but not for the treatment of impotence by intracavernosal injection. The Food and Drugs Administration in the USA does not allow the use of phenoxybenzamine by injection. Recently, further evidence has become available which shows that phenoxybenzamine given orally is carcinogenic in rats (personal communication, Flind, 1986). Consequently, although oral phenoxybenzamine has been in extensive use for many years in man and there has been no evidence of oncogenicity, I have ceased to use phenoxybenzamine for intracavernosal injection except in one patient for whom papaverine gives inadequate erection and who, when I first saw him, had a prostatic carcinoma with metastases.

Papaverine has been little used therapeutically except for CUMRI, and as far as I can discover it has not been subjected to tests of oncogenicity.

Discussion

Most of the users and some of the ex-users have expressed great pleasure at what the treatment has done for them. For a completely impotent man, coitus once per fortnight can be a great improve-

ment on no coitus at all, and for an incompletely impotent man, certainty of successful coitus once per fortnight can be a great improvement on never being certain of success. The fact that 54 men continue to use the treatment shows that they consider the benefits to outweigh the short-term side-effects. Only time will tell whether long-term harmful effects, especially fibrosis, are serious.

Choice and dose of drug

Papaverine is easier for the patient to dispense and has fewer side-effects than phenoxybenzamine. These are sufficient reasons for always trying papaverine first, and using it if it gives adequate erection. However, phenoxybenzamine remains useful in treating a minority of patients, because of its more prolonged action.

One patient gets good erections from 120 mg of papaverine but not from any smaller dose; on the other hand, one patient had priapism after only 18 mg. My present practice is to begin with 16 mg. If this is far from causing adequate erection, the rest of the ampoule (24 mg) is given on the other side 20 minutes later. The dose to be tried at the next consultation is estimated from the degree and duration of erection produced by the 16 or 40 mg given on the first occasion.

From January 1984 to February 1986 I used phenoxybenzamine only for patients in whom papaverine had given erections of insufficient duration. For such patients I began with 4 mg, and was willing to go up to 10 mg if smaller doses gave inadequate erection and no unacceptable side-effects.

Frequency of use

With four patients, I have yielded to their pressure and allowed the limit of 26 injections/year of papaverine to be slightly exceeded. One patient has, with my approval, greatly exceeded the ordinary ration for a single four-week period, but will thereafter not use CUMRI for many months because of his wife's absence. The majority of patients keep close to fortnightly use. A few use CUMRI considerably less often than I tentatively allow as safe. These either have no regular sexual partners or have absent or very defective penile sensation.

Relation between CUMRI and psychotherapy or counselling

Of the 127 patients, 28 have to my knowledge consulted a psychiatrist or psychologist practising sex therapy. They constitute over a third of those

patients without spinal cord injury or disease, and none of those with known spinal cord disorders. I have attempted no psychotherapy. I gave brief counselling to a few, but to the majority none at all beyond that which may have been implied by my questions and factual statements.

I hoped, from the first time I tried this treatment, that successful coitus with the help of CUMRI would improve the confidence of many patients in their sexual performance and that this would allow them to succeed without CUMRI. To my disappointment, only seven patients have improved other than after each CUMRI. In this respect my results are far less good than those reported by Virag *et al* (1983, 1984, 1985a).

Diagnostic significance of success and failure

If CUMRI causes full erection in an impotent man, this proves that the internal iliac arteries and their relevant branches outside the penis itself are adequate to support full erection when other conditions are favourable. It may not exclude atheroma in these vessels as a contributory factor in the impotence. The success of CUMRI presumably excludes cavernoso-venous or cavernoso-spongiosal shunts as the sole or principal cause of the impotence.

Success, even excellent success, does not exclude total destruction of the preganglionic peripheral nervous pathways of erection. One case establishes this. The patient had a complete flaccid paraplegia below T7 on the right and T6 on the left, following a road accident four years before CUMRI was tried. He had no trace of spontaneous or reflex erections; no lower limb, bulbocavernosus or anal skin reflexes; no tonic glandipudendal reflex (Gillan & Brindley, 1979); and no response of any skeletal muscle in the electroejaculation procedure (Brindley, 1981). Nevertheless, CUMRI with phenoxybenzamine (5 mg) caused his penis to stand perpendicular to his trunk, to be flexible only through 10° (i.e. to 170°), and to remain in this state for 70 minutes.

There is no direct evidence as to whether destruction of the postganglionic efferent pathways would prevent successful CUMRI. A theoretical argument suggests that it probably would not: the excitatory innervation of the relevant smooth muscle is mainly α_1 -noradrenergic, as the erectile action of α_1 -adrenoceptor blockers proves. If the innervation is lost, the α_1 -adrenoceptors should continue to be stimulated by circulating catecholamines, and the resulting smooth muscle activity should remain subject to annulment by phenoxybenzamine or papaverine.

Little can be concluded from failure of a single attempt at CUMRI with either drug, since the doses needed by different men differ greatly. If three attempts with increasing doses all fail, one can probably infer that the impotence is due to arterial occlusion or severe stenosis, or to a cavernoso-venous shunt.

Orofacial Dyskinesia, Cognitive Function and Medication

P. THOMAS and R. McGUIRE

The presence of tardive dyskinesia in a sample of 43 patients with schizophrenia and 37 psychopaths who had been hospitalised for many years and exposed to large amounts of medication was assessed while testing their cognitive function. Subjects who showed no evidence of abnormal movements performed significantly better on the test of delayed recall, but there were no differences in performance on any of the other tests of cognitive function used. Multiple regression analysis revealed that age and the total lifetime dose of neuroleptic medication received (in chlorpromazine equivalents) were the only variables to predict the Abnormal Involuntary Movement Scale score, although a large amount of variance in this variable was unaccounted for. The duration of treatment with neuroleptics did not predict AIMS score.

In the thirty years since the introduction of the phenothiazines there have been numerous reports of orofacial dyskinesias attributed to these drugs. There is little doubt that these disorders are now recognised more frequently. In 1955 Mettler & Crandell (1959) found a large number of neurological disorders in psychiatric patients, but no reference was made to any syndrome resembling tardive dyskinesia (TD). This is important because the study was performed before the introduction of the phenothiazines. Crane (1968) observed that 90% of cases of TD had been reported since 1964, and that the majority of sufferers were chronic schizophrenics—especially those who had received physical treatments such as ECT, leucotomy and insulin coma. His impression was that large doses of drugs were responsible, with increasing age also playing a part. Kane & Smith (1982) found the average prevalence of TD to be 20% in neuroleptic-treated patients, compared with 5% in untreated patients. These figures originated from 70 prevalence studies, which overall suggested that increasing age and female sex were the two factors most consistently associated with an increased risk of the disorder.

Despite this, many psychiatrists believe that TD is related to prolonged exposure to neuroleptics, an opinion propounded most forcibly by Klawans (1973), and supported for example by the findings of Smith *et al* (1978) who found a small but significant correlation between TD and total fluphenazine intake in patients over the age of 50. They suggested that dose schedule may be more important than total dose. More recently, Mukherjee *et al* (1982) have demonstrated a significant association between TD and the use of high potency or depot neuroleptics, and also increasing age.

Neurological impairment has long been considered aetiologically important in TD, although as Kane & Smith (1982) suggest there is not much evidence in support of this. Famuyiwa *et al* (1979) found that schizophrenic patients with TD performed less well on a paired associate learning test than those who did not have the disorder, although there were no differences between the two groups on other tests of cognitive function, nor in indices of cortical atrophy on computerised tomography (CT) scan. Similarly, Jeste *et al* (1980) in their CT scan study were unable to find evidence of cortical atrophy in schizophrenic patients with TD.

There are many problems in comparing the results of different studies. Definitions of TD differ in the extent to which a pure bucco-lingual-masticatory triad is specified, or in whether the tremors of parkinsonism or axial and limb movements should be included. Different selection criteria are used, so that experimental groups differ in age, duration of illness and treatment, and environmental factors which may influence the assessment of abnormal movements through anxiety and arousal. Most studies have been based on limited drug history data, relying either on medication at the time of the study or on detailed information collected over limited periods of time. Given the difficulties in determining precisely the total amount of medication received during the course of an individual's illness, a more detailed investigation of chronic neuroleptic administration in relation to TD is particularly important at a time when the use of such medication is being questioned. This study attempts to do this, and also to investigate the relationship between TD and cognitive impairment, by examining the following hypotheses:

1. Patients who exhibit TD perform less well on tests of cognitive function than patients without the disorder.

2. Using multiple regression analysis the total cumulative dose of neuroleptics can be used to predict TD score.

Method

Patients were selected from two sources: four long-stay wards in the Royal Edinburgh Hospital, and four long-stay wards in the State Hospital, Carstairs. All contained stable populations of male long-stay patients. The case notes of all patients were examined to exclude those over the age of 65 and those with a history of alcohol abuse, head injury, leucotomy, serious physical illness, organic psychosis, or mental subnormality. The research diagnostic criteria of Spitzer *et al* (1972) were applied to the remaining subjects, and the duration of admission, number of ECTs, and years of education obtained from their case notes. Detailed drug information was obtained from prescription sheets, which were available (for all but four subjects, who were excluded) as far back as the original admission. These were checked against entries from the medical notes and nursing notes, ensuring that dates and amounts of medication prescribed were as accurate as possible. Occasional medication was not recorded. For each of the six most widely prescribed neuroleptics (chlorpromazine, trifluoperazine, thioridazine, fluphenazine decanoate, haloperidol and flupenthixol decanoate) the starting date, dose, date of change of dose and date of discontinuation were noted. This information was summarised by a computer program which calculated the total equivalent dose for all drugs, using chlorpromazine equivalents (Davis, 1974).

Mental state assessments were performed using Wiles' (1976) glossary for the Brief Psychiatric Rating Scale (BPRS) of Overall & Gorham (1962), and the Abnormal Involuntary Movement Scale (AIMS) (Guy, 1976) was used to measure movement disorders on two occasions a month apart. This is a five-point rating scale measuring abnormal involuntary movements in seven areas, including the muscles of facial expression, tongue, jaw, lips, upper and lower extremities, neck, shoulders and hips; subjects were thus rated for such movements in body areas other than the orofacial region. All measurements were made 60 seconds after the subject had started a motivation test, and continued over a 60 second period. The test consisted of a boring and repetitive task in which subjects were given a page on which the letter X was printed more than 1000 times; they were then asked to circle as many as they wished, the score being the number circled before stopping. The purpose of this test was to assess the extent to which volitional impairment—an important clinical component of chronic schizophrenia—affected performance on the tests of cognitive function. The AIMS ratings were therefore made under standard conditions, with subjects unaware that they were being observed. Following this, the Paired Associate Learning test described by Inglis (1959), Williams' test of delayed recall (Graham-White, 1969), and Raven's (1960) progress-

	Schizophrenics	Psychopaths
Non-TD	7	22
TD	36	15

Corrected $\chi^2 = 14.23$, $P < 0.001$

ive matrices were given to all subjects. Data were analysed using the Statistical Package for the Social Sciences.

Results

Test/re-test reliability for the AIMS was satisfactory (Pearson's $r = 0.87$, $P < 0.001$). The presence or absence of movement disorder was established on the basis of the AIMS score over the two test periods; subjects with a total score of two or less were classified as having no abnormal movements. Eight subjects were excluded because they could only be tested on one occasion, leaving 25 subjects with no TD and 43 with TD. Although TD was more common in patients with schizophrenia a small number of psychopaths exhibited the disorder (Table I). A univariate model was used to identify relationships between TD and demographic data, treatment and test variables. With the exception of the total equivalent dose and amount of ECT received, which were both highly skewed, the distribution of all the dependent variables did not differ significantly from that of a normal distribution using the Kolmogorov-Smirnov 'goodness of fit' test. When the medication variable was transformed by taking its square root, it conformed more closely to a normal distribution.

Table II compares the demographic characteristics of the two groups. The TD group were significantly older, had been in hospital much longer, and had received more medication and ECT than the non-TD group, who had fewer psychiatric symptoms and performed significantly better on the motivation test than the TD group. On all three tests of cognitive function the TD group performed less well than the other group, although the differences were only significant for the delayed recall and its age-adjusted memory quotient. The greater age of the TD group appears to account for their performing less well on the progressive matrices; when the age-adjusted IQs are compared the differences disappear (Table III).

Discussion

These results are in accordance with other studies which suggest that TD is associated with increased age, longer hospitalisation, and exposure to large amounts of neuroleptics and ECT. As this is one of few studies to have attempted a direct measurement of the total intake of drugs, it is important to consider some of the weaknesses of this measure.

Although the prescriptions were checked for accuracy against two other sources of information, there was no way of checking that subjects had actually taken the prescribed medication. The only exceptions to this were the depot neuroleptics; however, the cumulative totals of fluphenazine and flupenthixol together accounted for only 16% of the total equivalent dose, so it must be assumed that the measure of oral medication was open to distortion because of the possibility that subjects might have failed to take it from time to time. It has to be assumed that non-receipt of prescribed medication was randomly distributed throughout the sample.

The fact that the TD group were older could account for them having received more medication, the link between TD and medication being secondary to the more important relationship between age and TD. At this stage multivariate techniques were used, with the AIMS score of all 68 subjects as the dependent variable in two multiple regression analyses. Initially, the variables used to predict the AIMS score were age, motivation test total score, total equivalent dose (square root), total time (years) on medication, duration of admission, BPRS score, and amount of ECT received. For each regression, solution plots of the residual values showed no evidence of non-linearity of the relationship.

The results of the first regression are given in Table IV; the best predictors of the AIMS score were age and total equivalent dose. To investigate the relationship further it was hypothesised that age was the most important variable, the value of the total equivalent dose as a predictor of the AIMS score being dependent on its own relationship with age. These variables were entered together in a stepwise hierarchical regression with age on the first step, and the square root of the total equivalent dose (STE) on the second. The result (Table V) reveals that both age and STE predict the AIMS score, age alone accounting for 21% of the variance, and STE accounting for a further 10%. This suggests that age and total medication are associated with tardive dyskinesia, but the interpretation of this regression should be tempered with caution. About one-third of the total variance in the AIMS score is explained

by these two variables, indicating that other factors unaccounted for in this study may make a considerable contribution. No attempt was made to measure the amount of anti-parkinsonian medication received by the subjects. TD may result not only from prolonged dopaminergic blockade, but also from the additional prolonged use of anticholinergic drugs. A further difficulty relates to the fact that subjects were assessed for TD while on medication, raising the possibility that the AIMS score is not representative of the severity of TD.

The poor performance of the TD group on the tests of delayed recall is further evidence of an association between TD and cognitive impairment. The results suggest that with increasing age and medication there is a greater likelihood of developing TD. However, the fact that the age-adjusted memory quotients were significantly worse in the TD group implies that the different amounts of medication received by the two groups, rather than age, may explain the differences in delayed recall. Anticholinergic drugs may produce confusion and memory impairment, especially in elderly subjects. Most patients in this study received such drugs to control extrapyramidal side-effects, although their use was not measured, and most neuroleptics possess anticholinergic properties to a varying extent. It is possible to speculate that the combined anticholinergic properties of neuroleptics and anti-parkinsonian medication to which the subjects were exposed might explain the relationship between total equivalent dose and delayed recall performance, although it must be stressed that this is speculative, given the absence of measures of anticholinergic activity in this study.

Although the degree of short-term memory impairment in these subjects was not great, it is important to bear this in mind when considering the need for long-term medication in a population who already have a multiplicity of handicaps. Caution should be exercised when contemplating the use of large doses of neuroleptics, especially with anti-parkinsonian medication in elderly subjects. The routine prescribing of combinations of such drugs should be questioned.

Conclusions

This study has shown that tardive dyskinesia may be associated with poor short-term memory performance. No relationship emerged between TD and the duration of exposure to medication, although both age and total amount of medication were found to predict the presence of TD. However, this study assessed dyskinesia when the subjects were still on medication. As it is quite possible that neuroleptics mask the manifestation of TD, this, together with the absence of any data concerning anti-parkinsonian medication, may have been responsible for the large amount of variance in the AIMS

score not explained by age and STE. This problem can only be overcome by examining subjects before and after their medication has been discontinued, and obtaining more detailed information on the prescription of anti-parkinsonian medication.

Acknowledgements

The authors are grateful to the Consultant Psychiatrists at the Royal Edinburgh Hospital and the State Hospital, Carstairs, for permission to study the patients under their care. We also wish to thank Professor R. E. Kendell for his helpful criticism at all stages of the study.

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine,¹ trifluoperazine² and haloperidol³ but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia⁴

DolmatilTM sulpiride

IN SCHIZOPHRENIA

scribing information Dolmatil Tablets: Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other. Each tablet contains 100mg sulpiride. **Indications:** Acute and chronic schizophrenia. **Dosage:** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning and evening) is recommended. **Predominantly positive symptoms:** Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice daily. **dominantly negative symptoms:** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily. **Mixed positive and negative symptoms:** 1mg-600mg twice daily. The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment. Clinical experience in children under 14 years of age is insufficient to permit specific recommendations. **Contraindications:** Phaeochromocytoma. **Warnings:** Extrapyramidal reactions especially akathisia have been reported in a small number of cases. If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary. After over a decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at high dose in a small number of patients; in aggressive, agitated or excited phases of the disease process, 'Dolmatil' may aggravate symptoms. Care should be exercised where hypomania is present. Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions:** Epilepsy - anti-convulsant therapy should be continued unchanged. Impaired renal function, as sulpiride is eliminated via the kidney. Pregnancy - the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed. **Product Licence Number:** PL 5299/0006. **Legal category:** POM. **Basic NHS cost:** 1p per day at dose of 600mg daily. **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. **de Marks of E R Squibb & Sons Ltd (Distributor) DOLMATIL - Trade Mark of SESIF Authorised User Delagrang Ltd. A SCHIZOPHRENIC.

Adolf Wölfli spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.

A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

100mg/ml

HALDOL*
haloperidol

50mg/ml

DECANOATE

Meeting the needs of the schizophrenic.

▼ **Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. **Use in Pregnancy:** The safety of haloperidol in human pregnancy has not been established. **Precautions:** Caution in liver disease, Parkinson's disease, pheochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methyldopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. **Side Effects:** In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50-100mg every 4 weeks; in moderate symptomatology 100-200mg every 4 weeks; in severe symptomatology 200-300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from **Janssen Pharmaceutical Limited**, Grove, Wantage, Oxon OX12 0DQ.

**SOME PEOPLE'S IDEAS ABOUT
ST ANDREW'S ARE AS DATED AS
THIS ENGRAVING**

Established almost 150 years ago St Andrew's has always been in the forefront of psychiatric developments.

In the 1800's it was the first hospital to totally abolish physical restraint. As early as 1927 it opened a separate unit for short stay patients. In the 1980's it has pioneered the application of behavioural methods to the management of a range of disorders including severe brain damage.

The Role of Zinc in Senile Dementia

C KENN and E. GIBB

Zinc deficiency has been reported in association with dementia and linked with its pathogenesis. A group of 45 elderly patients admitted to a mental hospital were given diagnoses in accordance with ICD-9, and their fasting plasma zinc levels were recorded. No difference was found in zinc levels between patients with diagnoses of senile dementia and those with other diagnoses.

Previous studies have shown the relevance of plasma zinc levels to psychiatric symptomatology, including acute syndromes associated with the administration of histidine (Henkin *et al*, 1975), prolonged total parenteral nutrition (Kay *et al*, 1976), acrodermatitis enteropathica (Nelder & Hambridge, 1975), and the continuing debate on the relationship of zinc to anorexia nervosa (Casper *et al*, 1980; Bryce-Smith & Simpson, 1984).

Srinivasan (1984) has summarised the role of trace metals in psychiatry, and Tiggelen (1983) reviewed the work linking zinc in the form of metallo-enzymes as a co-factor in the pathogenesis of dementia. However in much of the literature the diagnosis of dementia appears to have been based solely on the presence of cognitive impairment. The present study attempted to compare plasma zinc levels in patients with a diagnosis of senile dementia, using the ICD-9 definition (World Health Organisation, 1975), with those of a control group of patients with ICD-9 diagnoses.

Method

The sample comprised 45 patients over the age of 65, recently admitted to a mental hospital. They received a formal psychiatric interview, full cognitive assessment, and physical examination, and were given an ICD-9 diagnosis. Those with a diagnosis of dementia were rated on the Hachinski scale for arteriosclerotic dementia (Hachinski *et al*, 1974); in the absence of abnormal biochemical profiles, scores of less than 4 were taken as indicative of senile dementia and those of greater than 7 as of arteriosclerotic dementia. The Hachinski scale was thus used as an adjunct to ICD-9 to refine the diagnosis of senile dementia.

Fasting blood samples with minimal stasis were taken for a routine chemical screening, and for measurements of plasma zinc and plasma vitamin E levels (the latter is involved in the same oxidative pathways as zinc: the results of this part of the study will be reported in a later paper). Plasma zinc levels were measured using atomic absorption spectrophotometry (Whitehouse *et al*, 1982). The authors were blind to the results of the plasma zinc levels during the study.

Results

During the study period, eight patients were excluded for the following reasons: readmission (4), refusal to allow venepuncture (2), immediate hospital transfer (2), of the remaining 45, 22 (18 female, 4 male; mean age 81.1 years) met the ICD-9 diagnosis of senile dementia (ICD-290.0). The comparison group (17 female, 6 male; mean age 75.3 years) had the following ICD diagnoses: manic-depressive states (ICD 296; $n=13$), arteriosclerotic dementia (ICD 290.4; $n=2$), paraphrenia (ICD 297.2; $n=2$) acute confusional state (ICD 293.0, $n=2$), organic psychosis unspecified (ICD 290.9 $n=2$) residual schizophrenia (ICD 295.6; $n=1$), and Korsakov's psychosis (ICD 291.1, $n=1$).

The numbers in each group receiving drugs affecting zinc bioavailability (i.e. steroids, diuretics, and lithium) were comparable. No patient suffered acute infection or trauma. One patient in the senile dementia group had malignant disease, compared with two in the control group. No patient had evidence of diabetes mellitus.

The plasma zinc results are shown in Table I. Analysis was undertaken using the Wilcoxon unpaired test; the difference between the senile dementia sample and the comparison sample was not statistically significant.

Discussion

The total body content of zinc is about 2g, 80% of which is bound intracellularly in metallo-enzymes and cell membranes. Those at risk of developing deficiency are diabetics, alcoholics, pregnant and lactating women, and the elderly (Tiggelen, 1983).

1. Long stay mental hospital (all ages).

2. Serum zinc levels.

Although widely used, doubt has been cast on the validity of plasma zinc as a sole indicator of total body zinc status (*British Medical Journal*, 1981); Abdulla (1983) concluded that liver zinc may be a more accurate parameter of deficiency. Prasad (1983) states that plasma zinc is a useful indicator, provided the specimen is not haemolysed or taken in conditions of acute stress or infection. As plasma zinc is mainly protein-bound, levels of albumin and binding protein (α_2 macroglobulin) will affect estimations. No patient in this study had an elevated white cell count (taken as indicative of infection) or hypo-albuminaemia. In a younger age-group (23–62 years), Halsted & Smith (1970) found no instance of an elevated plasma zinc level in a variety of disease states.

The normal level of plasma zinc in adults is 12–22 $\mu\text{mol/litre}$; recent work has suggested mean levels in healthy elderly adults of 11 $\mu\text{mol/litre}$ (s.d. 1.2) and in healthy adults of 13 $\mu\text{mol/litre}$ (s.d. 1.8 (Bunker *et al.*, 1984). The levels in the present study compare well with Bunker's elderly group (Table II). The work of Kosman *et al.* (1979) showed a small but not statistically significant difference between plasma and serum zinc. Direct comparisons between studies using either measure are thus valid.

Burnet (1981) hypothesised a genetically based,

age-related progressive inability of neurones to incorporate zinc ions into DNA-handling enzymes, leading to an Orgel 'error catastrophe', producing defective protein synthesis and cell death. Thus 'pathological ageing' occurs. This has led to the current research interest in the role of zinc as a co-factor in the aetiology of senile dementia.

Previous workers have found evidence of lowered zinc levels in patients with dementia. In a study of recently admitted elderly patients with dementia, compared with those with depression, Hullin (personal communication) found significant lowering of plasma zinc in patients with dementia, with the albumin-bound fraction accounting for this difference. The serum levels were of an order similar to the present study. When screening a chronic hospital population, Hullin (1983) found a significant lowering of serum zinc in patients with dementia compared with patients with schizophrenia and affective disorder and controls (Table II).

In neither of these studies, however, were the types of dementias classified. Hullin also noted (personal communication) that patients with dementia in the latter study had average body weights lower than the other patients and some 20 kg lower than normal elderly people living in the community. This raises the possibility that the drop in serum zinc

could be concurrent with a nutritional defect or be an abnormality of metabolism as a consequence rather than a cause of dementia.

Tiggelen (1983) found similar results (Table II) in acutely admitted dementia patients (according to DSM-III classification), compared with healthy controls, but 70% of these had abnormal dexamethasone suppression tests. He therefore questioned the diagnosis of DSM-III dementia in his study group. He also suggested a superimposed undiagnosed depressive illness, and postulates that an abnormality of the hypothalamic-pituitary adrenal axis caused by, or could cause, zinc deficiency.

There are no obvious reasons why the levels of plasma and serum zinc quoted in the various studies differ so widely. The most comparable study to this one is that by Hullin (personal communication) and, aside from the differences in classification mentioned, it is unclear why the two studies have produced contrasting results. Further research into this area is clearly warranted.

Temporary Urinary Incontinence in the Acute Psychiatric Patient Without Delirium or Dementia

G. E. BERRIOS

In a prospective study of the 295 admissions in one year to an acute psychiatric ward, 14 subjects without delirium or dementia were found to have developed temporary urinary incontinence. When compared with matched controls ($n=56$) the incontinent patients were found to be suffering from psychosis ($P<0.0002$) and to have a history of childhood enuresis ($P<0.01$). Compared with psychotic controls ($n=22$), the incontinent patients were older ($P<0.05$), they had been exposed to a greater variety of treatments ($P<0.01$), and they had received more thioridazine ($P<0.04$).

It is not a rare clinical observation that psychiatric patients without delirium or dementia may exhibit episodes of urinary incontinence during the acute stage of their condition. The symptom has a good prognosis. Clinicians tend to explain this temporary disorder of micturition in terms of disturbed and disinhibited behaviour, stupor, psychotic disorientation, aggression or psychodynamic regression. Although of some relevance, it is unlikely that these factors are more important than variables such as central neurotransmitter dysfunction (Ambrosini, 1984), medication (Van Patten *et al.*, 1973; Nurnberg & Ambrosini, 1979) and medical history.

This paper reports a study designed to identify the clinical characteristics of acute psychiatric patients not affected by delirium or dementia who develop temporary urinary incontinence during the acute phase of their illness.

Method

This prospective study was carried out in a 30-bed general admission ward in Fulbourn Hospital, Cambridge, with a catchment population of about 125 000. There were 295 admissions during the period covered by the study (1 January 1984-31 December 1984).

Patients who met the following entry criteria were selected for the incontinent sample:

1. At least three episodes (diurnal or nocturnal) of urinary incontinence, defined as 'involuntary loss of urine constituting a social or hygienic problem' (Isaacs & Walkey, 1964)
2. The three episodes to have occurred within a period of no more than 48 hours
3. Absence of acute confusional state or dementia (ICD9)

A control sample of 56 patients was selected from the total cohort ($n=295$). As soon as a patient met the criteria

for urinary incontinence, four other patients were chosen as his/her controls from amongst fellow patients, according to the following criteria:

1. No clinical evidence of acute confusional state or dementia
2. Admission date no more than one week before or after that of the incontinent patient

If more than the needed number met the criteria, the four control patients were selected randomly.

A specially designed data sheet was completed for both the incontinent patient and his/her four controls. The form collected data on five areas: general, medical history, psychopathology, ICD9 diagnosis (as made by the consultant in charge), and treatment. Statistical analysis of the data was carried out by means of the Unistat Software Package for CPN.

Results

Fourteen patients (4.74%) met the inclusion criteria for urinary incontinence. There was no difference in age, sex, presence of urinary disease, parity, orthostatic hypotension or previous history of adult incontinence between the experimental group and the control group of 56 patients (Table I). However, the incontinent sample showed a higher proportion of patients with a history of childhood enuresis ($P<0.01$; Table I) and a higher proportion suffering from psychotic illness ($P<0.0002$; Table II).

There were 22 psychotic patients amongst the 56 controls, and this psychotic sub-group was compared with the incontinent set. No differences were found between the two groups in terms of family history of psychiatric illness, number of previous episodes (Point biserial correlation coefficient, $rpb=0.0012$; NS), duration of present episode ($rpb=0.0091$; NS), distribution of diagnoses (Table II), or symptomatology (Table III). However, the incontinent patients were significantly older ($rpb=0.28$; $t=1.75$; $P<0.05$) and had received a greater variety of treatment

TABLE I

($P < 0.01$; Table IV). More of them had received thioridazine ($P < 0.04$; Table V) and the dosages prescribed tended to be larger ($t = 2.155$; just short of $P < 0.05$).

Discussion

The entry threshold for urinary incontinence used in this study was sufficiently high not to allow into the sample patients with occasional urinary loss. None of the 14 incontinent patients were suffering from delirium or dementia (each patient was examined by

at least two consultant psychiatrists). Three were found to be disorientated during the acute stage of their condition (two depressive and one manic); there was no evidence of organic aetiology, however, and the symptom cleared up after treatment. On discharge all subjects had recovered from both the psychiatric episode and the urinary incontinence.

The first conclusion of clinical value is that psychotic patients are more prone to developing temporary urinary incontinence than non-psychotic

TABLE III

patients; the second is that the type of psychosis does not seem to be a relevant factor; the third is that accumulation of treatments (irrespective of their nature) seems to be related to the appearance of urinary incontinence. However, the conclusion that there is a cause-effect relationship between

an accumulation of treatments and incontinence, although tempting, cannot be drawn from our data. The alternative hypothesis is that such an accumulation simply reflects the severity of the psychotic illness and that the latter is ultimately responsible for the micturition disorder. It must be remarked,

TABLE V

Past and current treatment of 14 incontinent patients (all psychotic) compared with that of 22 psychotic controls: figures indicate number of patients receiving each treatment

* $P < 0.04$.

however, that no difference was found between the incontinent group and the control sample in terms of family history of psychiatric illness ($\chi^2 = 1.40$; NS), number of previous episodes ($rpb = 0.00129$; NS), duration of current admission ($rpb = 0.00919$; NS) or symptomatology.

Thioridazine had been prescribed more often to the incontinent sample ($P < 0.04$). An association

between this neuroleptic and an increased incidence of urinary incontinence in psychiatric patients has been reported anecdotally (Ananth *et al*, 1971; Renshaw, 1971; Crittenden, 1972) but no prospective study of this association seems to have been published.

It has recently been suggested that the central control of micturition depends upon a noradrenergic-dopaminergic balance, with dopamine agonists increasing control and antagonists increasing the likelihood of incontinence in predisposed individuals (Ambrosini, 1984). Why thioridazine should have a more marked effect than other neuroleptics is unclear.

Developmental delays in the acquisition of control of micturition have been mentioned as a major vulnerability factor; it is therefore of some interest that the present study found that a significantly higher number of incontinent patients had been enuretic during childhood. Orthostatic hypotension has also been mentioned as a concomitant symptom of urinary incontinence but our study showed no difference in this regard between the incontinent and the control groups.

Depression in Schizophrenia: A Study of Prevalence and Treatment

R. ELK, B. J. DICKMAN and A. F. TEGGIN

In an investigation of white, coloured, and black patients admitted to a psychiatric hospital, the prevalence and treatment of depression in schizophrenia was assessed and found to be 30% in group of acute, nuclear schizophrenics. While the prevalence was similar in the three groups, depression was clinically under-detected in black patients.

The presence of depression among schizophrenics has been recognised since the times of Kraepelin and Bleuler, and many clinicians feel it is an integral part of the illness (Knights & Hirsch, 1981; Planansky & Johnston, 1978). Though reports of the prevalence of depressive symptoms vary, recent evidence suggests that it is considerable (ibid and Roy *et al.*, 1983), and that there is a significant suicide risk among depressed schizophrenics. As such, it warrants more attention by both clinicians and research workers (Donlon *et al.*, 1976). An opportunity for a detailed examination of this phenomenon arose out of an investigation of sequentially selected acute schizophrenic patients admitted to a psychiatric hospital in Cape Town, South Africa (Teggin *et al.*, 1985).

As this group included white, coloured, and black (as defined by the Population Registration Act, 1950 (as amended)) patients, it was possible to focus on the issue of depression among blacks. There is diversity of opinion about the prevalence of depression in this group; early reports (Buchan, 1969; Prince, 1968) seemed to indicate that it occurred rarely, although recent evidence contradicts this (Leff, 1973; Singer, 1975).

The aims of this investigation were to determine the prevalence of depression among a specific group of acute schizophrenics; the extent to which depression was clinically treated; and whether the black groups differed from the other two in terms of both prevalence and treatment of depression.

Method

The Present State Examination (PSE) and the CATEGO computer programme (Wing *et al.*, 1974) were used both to select patients for inclusion in the present analysis and to assess their mental state. Only those schizophrenics with a CATEGO class 'S' diagnosis, i.e. characterised by either the presence of first-rank symptoms or other unequivocal symptoms of schizophrenia, were selected. Patients with coexisting organic conditions, e.g. epilepsy or drug or alcohol abuse, were excluded. Thus a circumscribed group with a clearly defined schizophrenic disorder was focused upon. The total sample comprised 56 patients (19 white, 15 coloured, and 22 black).

The PSE was conducted by a research team within three days of the patient's admission to hospital, while the patient's clinical diagnosis and management remained in the hands of the responsible clinician.

It is often difficult to distinguish between depressive symptomatology and certain symptoms of schizophrenia (Donlon *et al.*, 1976; Knights & Hirsch, 1981). For example, both depressed and schizophrenic patients may exhibit inefficient thinking or social withdrawal. It was therefore decided to select a sub-set of PSE symptoms—depressed mood (symptom 23) combined with observed depression (symptom 121)—to obtain a finer indicator of depression.

Information on the treatment of depression (using anti-depressants or ECT) by clinicians was obtained from an examination of the patients' hospital folders.

Results

Using the sub-set of depressed mood combined with observed depression, 30% of all the patients were found to be depressed, with no significant differences between the ethnic groups; 16% expressed suicidal ideas or acts (symptom 25).

While depression was treated by clinicians in 59% of the depressed group, further analysis revealed a significant difference between the black and the other two groups: 82% of whites and coloureds, compared with only 17% of blacks, were treated for their depression ($P < 0.05$; Fisher's Exact Test). The possibility that clinicians were using other criteria (such as the vegetative symptoms of depression) to detect depression in the black patients was considered. However, as only three black patients were treated they constituted too small a group for any clear patterns to emerge.

Discussion

Despite the small sample size, this investigation had the advantage of a methodology that enabled independence of the clinical and research judgements. The prevalence of depression found in this study confirms that a substantial number of acute schizophrenics are sufficiently depressed to warrant treatment. Similarly, the relatively high rates of suicidal ideation emphasises the need for an awareness of the risk of suicide in schizophrenia. The rate of treatment of depression by clinicians is similar to

that reported by previous investigations (Knights & Hirsch, 1981).

The finding that depression occurred as frequently in black patients as in other groups confirms recent related evidence, and is an important finding with obvious clinical implications. Despite this similarity, the low percentage of depressed blacks that were treated by the clinicians warrants some discussion. As the majority of clinicians do not speak Xhosa (the language spoken by the majority of black patients in the Cape), interpreters are vital to the understanding of the patient. The shortage of interpreters in the hospital frequently results in clinicians spending limited time with the interpreter, or having to interview black patients without one. Therefore, in dealing with schizophrenic patients, clinicians are likely to focus on psychotic symptomatology and

not investigate other symptoms in any depth. In addition, since many black patients may use metaphorical or somatic terms to describe feelings of depression (Gillis *et al.*, 1982), it is possible that the clinicians do not attempt to elicit depressive symptoms. This study, however, illustrates that not only are depressed mood and observed depression present in black schizophrenics, but that with the use of skilled interpreters these symptoms are ascertainable.

Electro-Oculogram Changes at the Switch in a Manic-depressive Patient

S. M. HANNA, F. A. JENNER and L. P. SOUSTER

The correlations between eye movements on the EOG of a patient with a 48 hour cycle of manic-depressive type are described. They are used to confirm the fact that his switch from one state to another occurred at the same time of night whether he was awake or asleep.

Eye movements with a frequency of $\frac{1}{2}$ –1 Hz have been related to mood state in some patients with periodic psychoses, in whom it can be a good indicator (Gjessing *et al*, 1967; Stones *et al*, 1980a,b). This paper presents studies on one manic-depressive psychotic patient, who had a persistent and predictable 48 hour cycle. Information on this patient has been published previously (Goodwin *et al*, 1964; Harding *et al*, 1964, 1965, 1966; Jenner *et al*, 1967, 1968), following a decade of observations by clinical staff and over 300 electrocephalogram (EEG) recordings. However, some details of the EEG and electro-oculogram (EOG) findings have never been fully described, and may have more general interest, as well as providing information on factors relevant to less extreme and predictable illnesses. In particular, they illustrate that a timing mechanism is involved, but one which is independent of being awake or asleep.

Methods

The patient was studied between the ages of 48 and 58. He had a precise 48 hour cycle of manic-depressive type, which had persisted for 11 years, but was not on medication for most of the period of this study. The method of mood scoring was described by Jenner *et al* (1967). Nursing staff rated the patient's mood as follows: abusive, constantly shouting, quarrelsome and demanding (+3); abusive, expresses paranoid ideas and talks loudly (+2); overactive and overtalkative but good-natured (+1), normal or difficult to assess (0); quiet but makes spontaneous remarks (–1); lethargic, responds to remarks and reads the paper occasionally (–2); almost totally inactive but responds to direct approaches (–3).

Eye movement recordings were obtained using an EEG machine (time control 0.3 s high frequency 70 Hz, amplitude 100 μ V/cm). Electrodes were attached to the frontal and occipital areas to record the sleep stages, and to the orbit areas for the EOG. The montage used was the standard 10–20 system; channels 1, 2, 3 and 4 were respectively Fp1–F8, Fp2–F7, F2–C2, and C2–O2 (mid-occipital). Hence, at night, eye movements were recorded from the leads on the orbits and two EEG channels were taken from the frontal and occipital areas. A fifth channel was recorded for an electromyogram and used to confirm the stages of rapid eye movement (REM). Sleep latency and dream latency were assessed, and scored according to international criteria (Rechtschaffen & Kales, 1968).

Results

The scores of mood were found to be extremely predictable and reliable, with the patient in mania one day and depression the next; the mood change-over occurred at night. There was a persistent pattern of falling asleep later, when manic on retiring (sleep began later than 2300 hrs), and earlier when depressed (before 2300 hrs). The dream

FIG 1 The results of 'blind' classification of EOG records into those dominated by (cross-hatched), showing some (cross-hatched with dotted lines) and showing no (blank) $\frac{1}{2}$ –1 Hz eye movement. R is the number of records assessed from each mood state.

delay in this patient was 15.1 min (sd 8.6), which is shorter than usual (Dement & Kleitman, 1957; 67 min; Oswald & Thacore, 1963: 1 hr; Feinberg *et al*, 1967: 69 min; Kahn & Fisher, 1969: 59 min). There was no difference at the 5% confidence level between the dream delays in the manic and depressive moods (mania 13.35 min, sd 7.1, depression 16.6 min, sd 9.8).

The EOG was dominated by $\frac{1}{2}$ –1 Hz eye movements when the patient was awake and in mania, but their presence in the EOG was negligible when he was depressed. Fig. 1 shows the relationship between presence of $\frac{1}{2}$ –1 Hz eye movements (assessed blindly) and mood. The proportion of $\frac{1}{2}$ –1 Hz eye movements was assessed in records of EOGs taken in three mood states: elated (+3), normal (0), and depressed (–3).

The records to be analysed for the validity of the correlation between the presence of EOG $\frac{1}{2}$ –1 Hz waves and the mood were taken from daytime recordings at 0800 hrs; the first 20 minutes of each was studied. They were selected because they had 20 minutes of a satisfactory continuous record. A similar number of manic, depressed, and treated days was selected. They were then shuffled and read blindly in terms of the EOG trace. Admittedly a clue was given by the EEG alpha rhythm, but the EOG was easier to assess and was the more reliable indicator, and the one on which we depended for Fig. 1. The correlation between those daytime recordings and mood, although striking, is not as high as that based on the first five minutes of the waking state, which consistently predicted the day's behaviour.

Figure 2 shows an example of the instantaneous changes which occurred at the switch. For these recordings the patient was kept awake at night and the EOG continuously

FIG. 2 The EEG and EOG at the time of a mood change switch, when the patient was kept awake for the appropriate part of the night.

recorded; the pattern altered abruptly at the mood change-over, which was between 0230 and 0300 hrs. The $\frac{1}{2}$ -1 Hz pattern would either disappear or appear suddenly, depending on the direction of the mood change. This phenomenon was recorded on eight nights, with identical results. On 209 occasions the EOG on waking was instantly that of the anticipated and observed mood, on nine occasions it was equivocal (i.e. showing some but not persistent $\frac{1}{2}$ -1 Hz recording for 5 mins), while on four occasions there was the paradoxical state (i.e. the mood and EOG were then inconsistent).

The sleeping EEG nearly always (99% of 204 satisfactory records) showed a period of REM sleep between 0230 and 0300 hrs, when the change was expected to take place. On the one occasion when that was clearly not so, there was a cycle defect, and the patient was manic both on retiring and on rising; there was no period of REM sleep at the critical time on that night. On one night, when the patient's mood swing was very obviously from a more aggressive mania than usual to a very profound, almost stuporose depression, he had a period of REM sleep which was longer than usual (51 min).

Cycle defects such as that mentioned above were rare (fewer than one/year). The patient would have two or more days of hyperactivity, and recommence the 48 hr cycle on the second or subsequent nights. Less rarely, the time of change-over from hyperactivity to inactivity was delayed from the usual time by as much as 10-11 hours (this occurred 10-12 times a year). The cycle was then

corrected on the following night, with the usual change-over of mood.

Discussion

The relationship between circadian and similar biological rhythm cycles of metabolism remains intriguing but obscure. The rare and rapidly cycling patients, especially those with 48 hour rhythms such as the one reported here, continually raise the possibility that their study will give an insight into some of the temporal aspects of cerebral organisation and affective psychosis.

The fact that this patient had eye movements on his EOG recordings when manic and not when depressed, and the fact that they began the moment he awoke manic or ceased the moment he fell asleep when manic, and then appeared as soon as half aroused, gives objective evidence that the time of switching was, for a biological phenomenon, peculiarly precise and independent of the sleeping state. The switch, when it occurred during sleep, was probably associated with paradoxical sleep.

Paschalis *et al.* (1980) described another patient who showed a sliding time of change, always in the daytime, in a cycle of almost 48 hours. The time of switching unusually jumped eight hours, and so 'never' occurred during sleep. This, as Paschalis *et al.* report, is different from the majority of patients with 48 hour cycles described in the literature. The collection of several such reports—which must be of isolated cases because the phenomenon is rarely so precise in clinical practice—may lead to an illuminating theory, or at least to heuristically valuable models. These models must ultimately, if complete, 'explain' the features of these cases which are similar but unrelated in detail.

This patient is now dead. His remarkable response to lithium therapy has been reported (Hanna *et al.*, 1972), but not the fact that in his terminal illness (with a carcinoma of the stomach), despite our inability to detect mood changes, he only requested opiates on alternate days.

A Study of Violent Behaviour Among In-Patients in a Psychiatric Hospital

M. PEARSON, E. WILMOT and M. PADI

A retrospective analysis of the violent incident forms returned over a one year period in a psychiatric hospital recorded 283 incidents involving 144 patients. Almost all were of a petty nature, none leading to lasting injuries. Compared with the average daily in-patient population, offending patients were more likely to be male, to be less than 45 years old, and to have a diagnosis of schizophrenia.

Violent incidents are almost daily occurrences in a district psychiatric hospital, but apart from Fottrell's 1980 survey of three hospitals there has been little research published on violent behaviour among psychiatric in-patients in the UK. This survey attempts to build on Fottrell's work, with the aim of identifying which patients, in which setting, become involved in violent behaviour.

Method

Violent incident forms returned for in-patients at the Central Hospital, Hatton, Warwickshire over the period 1 June 1983 to 31 May 1984 were analysed, and additional data collected during the next three months. The hospital provides all the in-patient psychiatric facilities for a semi-rural area with a population of about 200 000. Three acute admission wards, six long-stay wards, nine psychogeriatric

wards, an alcohol treatment unit, a rehabilitation unit and a ward for the adult mentally handicapped were included. A Regional Secure Unit was the only in-patient ward not included in the study, this treats forensic patients, and is not used as a place of transfer for violent or acutely disturbed patients from the rest of the hospital.

Nursing staff at the hospital are instructed to complete a violent incident form whenever a patient intentionally commits an act that leads to damage to property or injury to another person. As our study was retrospective, we were not able to include any measures to improve the reliability of reporting. Thresholds for reporting violent incidents differ, we consider them to be higher on acute admission wards, compared with the rest of the hospital. To ensure that no serious incident had gone unreported, we asked senior medical and nursing staff to list any such incidents they knew of. No serious omissions were noted.

The violent incident form provides information on the name, sex, status, and age of the patient initiating the incident, the time and date, any injuries to people or damage to property, and the nurses' assessment of any

precipitating events and action subsequently taken. All forms are countersigned by the ward doctor or duty doctor, who must examine and report on any injuries which have occurred. We applied Fottrell's three-stage classification of the seriousness of injuries to the data.

We estimated the characteristics of the average daily in-patient population over the 12 month period of study in the following way. The average daily number of in-patients ($n=435$) and their ward distributions were determined from the 12 end-of-month return figures at the records department. The age, sex, and diagnosis of all in-patients at the end of the study ($n=420$) was determined from case notes, and the figures scaled up proportionally. This method will produce some errors on the high turnover wards, where sampling of the characteristics of the in-patient population at more frequent intervals during the one year period is required to increase the accuracy of the 'average population' data.

During the period of study a total of 1220 in-patients passed through the hospital. Since the characteristics of the majority (800) of these were unknown, only those of the

'average population' are given as an approximate guide, and no statistical tests are used when comparing this group with the patients involved in violent incidents.

Results

A total of 283 violent incident forms were returned over the one year period, an average of 24 per month. The majority of incidents involved either no visible injury (69.6%) or minor injuries such as superficial cuts and bruises, which did not require further investigation (29.0%). The four serious injuries consisted of a deep cut, two cases of severe bruising, and a cigarette burn; none of them resulted in long-term injuries.

The commonest victims of violence were fellow patients (114), closely followed by nursing staff (92); there was a tendency for injuries to fellow patients to be more severe than injuries to nursing staff. The 283 incidents were perpetrated by only 144 patients; 103 were responsible for only one incident each, while 41 were multiple offenders. Amongst the latter one stands out as exceptional, with 33 reports of violence. This was a young schizophrenic woman from an acute ward.

Table I compares the patients who behaved violently with the average population: the former were more likely to be male young (under 45), have a diagnosis of schizophrenia, and to come from non-geriatric wards. A comparison of the characteristics of single and multiple offenders did not reveal any differences between the two groups.

An analysis of the times of day at which violent incidents occurred showed that they were distributed fairly evenly throughout the morning, afternoon, and evening, with very few at night. The hours in which violence peaked corresponded with the times when meals were being served on the wards.

Discussion

Violence leading to serious injury was rare throughout the one year period. This finding is in keeping with most other studies (Armond (1982), Fottrell (1980), and Folkard (1957)). However, Aiken (1984) found six incidents leading to third-degree injuries to staff on a 17 bed locked acute admission ward at the Maudsley Hospital over a six month period.

The most important finding here is the excess of violence amongst schizophrenic patients compared with the hospital population. Higher rates of violence amongst these compared with other diagnostic groups have been noted by Fottrell (1980) and by Hafner & Boker (1973). In Fottrell's survey 39% of the patients who behaved violently were schizophrenic, but it is not possible to say whether this is more than expected, since the proportion in the overall hospital population was not recorded. In our survey 56% of the patients who behaved violently were schizophrenic and, at the time of the end of the survey at least, only 30% of the in-patient population had this diagnosis. Since the rate of turnover

of schizophrenic patients is relatively low compared with that of other diagnostic groups, we believe that the average figure of 30% is fairly accurate. The excess of schizophrenics among the violent group is therefore significant.

The findings of excess violence amongst the younger age-groups and on the acute wards were expected, but the excess on the medium and long-stay wards was more surprising, and warranted further investigation. We found it was largely due to a small group of eight patients, who all had a diagnosis of schizophrenia. They had active delusions and hallucinations, which were resistant to medication and which seemed to precipitate their violent behaviour. This group contributed 56 incidents over the one year period, and continued to offend at about the same rate over the subsequent six months. We feel that they constitute an important group for further study and intervention.

Fottrell found that staff were the commonest victims at all three of the hospitals he studied, whereas in our survey patients more commonly assaulted fellow patients than members of staff. This probably reflects the differences in the types of ward populations studied. Of the violent incidents in our study, 71% occurred on the medium, long-stay, and psychogeriatric wards, which together account for 73% of the in-patient beds. The ratio of nursing staff to patients is much lower on these wards, so that when violence occurs in this setting it is more likely to be directed at fellow patients than at the nursing staff.

The timing of incidents at the Central Hospital shows a more even distribution than in Fottrell's study, where 30% of all incidents occurred between 7 a.m. and 9 a.m.; this period accounted for only 16.6% of the incidents at the Central Hospital. However, we agree with Ekblom (1970) that it is at times when patients are together on the ward, with little therapeutic activity, that violence is most likely. The violent incident form contains a section asking whether the nursing staff could identify any events which precipitated the incident. When such events were mentioned, they most often included arguments over food and personal space which occurred at meal times; this type of incident probably accounts for the peaks of violence at meal times. However, within the three acute wards the commonest precipitating events were patients being detained on the ward or given medication against their will—a finding in keeping with those of Aiken (1984).

Fottrell's finding that only a small percentage of the patient population behave violently was confirmed; in his study only 171 of the 1661 patients

treated in a one year period committed violent incidents (10.3%). At the Central Hospital 144 patients were involved, out of a total number of 1220 in-patients over the year (11.8%).

The Influence of Psychological Factors on the Opiate Withdrawal Syndrome

G. T. PHILLIPS, M. GOSSOP and B. BRADLEY

Psychological and drug-related variables and their effect on the severity of withdrawal symptoms were examined in a group of addicts being withdrawn from opiates on an in-patient drug dependence unit. Two psychological factors—neuroticism and the degree of distress expected by the patient—were related to subsequent severity of symptoms. Both are anxiety-related, and may serve to amplify withdrawal symptoms. Surprisingly, drug dose was unrelated to symptom severity.

A principal feature of opiate addiction is the withdrawal syndrome, which is often regarded as one of the defining characteristics of such an addiction. The withdrawal syndrome is recognised and described in general terms in most accounts of addiction, but has not been fully investigated. There are many aspects of it that require further research.

The fact that physiological symptoms such as increased perspiration, lacrimation, abdominal cramps, nausea, and diarrhoea are prominent features of withdrawal led the authors of early formulations to emphasise its 'physical' aspects; this is reflected in the use of the medical term 'syndrome'. However, research has shown that psychological

factors may also have a powerful effect on aspects of the withdrawal syndrome.

As early as 1927, Pavlov noted that classical conditioning of morphine-induced responses had been observed by Krylov; subsequently, Wikler (1948) proposed a theory that relapse after detoxification was due in part to conditioned stimuli that elicit aspects of the withdrawal syndrome. Many studies have since confirmed this, and have extended understanding of the role of conditioning in the addictive disorders (O'Brien, 1976; O'Brien *et al.*, 1977; Siegel, 1979).

Kleber (1981) stated that other psychological factors such as the patient's personality, his state of

mind at the time of withdrawal, the setting in which withdrawal takes place, and his expectations of the severity of the symptoms may all have a marked effect on the severity of the withdrawal. Indeed, Kleber suggested that their cumulative effect can be as great as that of any pharmacological factors. This observation is in accord with the views of many experienced clinicians, but has not received adequate empirical investigation. The present study looks at Kleber's suggestions as they apply to the withdrawal syndrome experienced by a group of opiate addicts being detoxified from drugs as in-patients on a graduated oral methadone reduction schedule.

Method

All heroin and methadone addicts admitted to the in-patient Drug Dependence Clinical Research and Treatment Unit of the Bethlem Royal Hospital in a five-month period in 1984 were studied. There were 34 such admissions, two of whom were excluded since they were drug-free at the time of admission; 24 were male and 8 female. Their average age was 25.9 years (range 18–38). The length of time for which they had used opiates varied between 1–19 years, with a mean of 5 years. In these respects the subjects are similar to the wider population of addicts attending London Drug Dependence Clinics (Gossop *et al*, 1984; Blumberg, 1981).

On admission, all subjects underwent a three-day assessment period during which their need for opiates was assessed. The initial daily dose level of methadone was established on the basis of clinical examination by a psychiatrist and of nurses' observations. The response to this trial dose was closely monitored during a three-day period, and if there were signs of intoxication or of opiate withdrawal the dose was adjusted as necessary. All subjects were then withdrawn from their drug of dependence over a 21-day period. During the withdrawal programme addicts received oral methadone three times a day on a linear reduction schedule. During the first 50 days they completed a self-report questionnaire designed to measure symptoms of opiate withdrawal. A version of this was used in the study reported by Gossop *et al*, (1984). The questionnaire contained 32 signs and symptoms; subjects were required to rate themselves on each item as it applied during the preceding 24 hours, using a four-point scale (nil, mild, moderate, severe). The 32 items were: feeling sick; vomiting; diarrhoea; poor appetite; dry mouth; stomach cramps; restlessness; eyes sensitive to light; headache; drowsiness; dizziness or giddiness; fainting attacks or lightheadedness; stiffness of arms and legs; spontaneous twitching (contraction) of muscles; trembling hands; feelings of coldness; feeling of unreality; 'gooseflesh'; hot and cold flushes; increased sweating; runny nose; trouble starting urination; passing more than usual quantity of urine; heart pounding; fatigue or tiredness; muscular tension; aches and pains; weakness; yawning, sneezing, runny eyes; and insomnia.

At the time of admission all subjects completed a further

brief questionnaire, in which they were asked to state on a four-point scale the severity of the withdrawal symptoms they expected to experience. They also completed the Eysenck Personality Questionnaire (EPQ) (Eysenck & Eysenck, 1975).

Results

A stepwise regression analysis was performed, in which the extraversion, neuroticism, and psychoticism scales of the EPQ, length of opiate use, withdrawal dose of methadone, age, and expected withdrawal distress were regressed against the maximum total withdrawal score obtained for each subject during the measurement period. Two variables were found to be significantly related to intensity of the opiate withdrawal syndrome—neuroticism, and the level of withdrawal distress expected, accounted for 36% (R^2) of the total variance in the withdrawal score. Neuroticism accounted for 24% of this (d.f. = 8.41, $P = 0.007$), and expected distress for 12% (d.f. = 7.0, $P = 0.04$). The main drug-related measures—methadone dose and length of opiate use prior to admission—were not significantly related to intensity of withdrawal. The mean value for methadone dose was 38.4 mg, with a range of 10–60 mg; more than two-thirds of the doses were within the 30–45 mg range. This finding is directly comparable to those of other studies at this clinic (Johns & Gossop, 1985, McCafferty & Gossop, 1981).

In a further analysis, simple correlation coefficients were calculated between the maximum withdrawal score and each of the other measures. The highest correlation was between neuroticism and withdrawal distress ($r = 0.46$), and this was the only significant result ($P = 0.01$). Duration of opiate use ($r = 0.36$) and expected distress ($r = 0.35$) were both slightly above the 5% level of significance ($P = 0.054$ and 0.066 respectively). Methadone dose was not correlated with maximum withdrawal distress ($r = -0.19$).

Discussion

These results confirm Kleber's observation (1981) that psychological factors play a major role in the opiate withdrawal syndrome: in particular, they show that the personality factor of neuroticism and the addict's expectations about withdrawal are strongly related to the maximum level of withdrawal distress subsequently experienced during detoxification.

Both these measures may be seen in broad terms as anxiety-related. Eysenck's neuroticism factor has been described as reflecting the reactivity and lability of the autonomic nervous system (Gossop, 1981); Eysenck & Rachman (1965) suggest that high neuroticism scorers are predisposed to respond more strongly, more lastingly, and more quickly with their autonomic nervous system when presented with stressful stimuli. In this respect, high levels of neuro-

ticism may act to amplify the response to opiate withdrawal. The same sort of process may also underlie the link between the addict's expectations about detoxification and his subsequent response to drug withdrawal. Eiser & Gossop (1979) found that most addicts were extremely frightened of withdrawal, and believed that this was also true of other addicts. The present study shows that the more frightened of withdrawal the addict is, the more discomfort he is likely to report during the actual process of being withdrawn from drugs.

It is interesting that in the regression analysis both the dose of methadone prescribed prior to the withdrawal programme and the length of opiate use were found to be unrelated to maximum levels of withdrawal distress, although there was a positive (but non-significant) correlation between duration of opiate use and withdrawal distress when simple correlation coefficients were calculated. Kleber (1981) suggests that duration of use may be related to withdrawal severity only up to a certain point, and that after two to three months it has little effect. It is more surprising that the dose of methadone was unrelated to severity. Kleber also states that the larger the daily dose of opiates, the more severe the withdrawal syndrome; this has been universally assumed, and seems almost self-evident; However, it is surprisingly difficult to find any empirical research to substantiate the claim. Several other definitive sources make the same link between dose and withdrawal severity, but like Kleber fail to cite any reference to original research (Goodman & Gilman, 1980;

Martindale, 1982; Wikler, 1980). The findings of the present study, coupled with the lack of empirical evidence, point to the need for further research to clarify this issue.

The main clinical implication of these results is that attention should be paid to the psychological state of the addict before and during the process of drug withdrawal. Research in other areas of medical psychology has shown that giving patients accurate information about what they may expect after surgical procedures reduces the pain and discomfort they subsequently experience (e.g. Melamed, 1977). Similarly, providing accurate information reduces the distress experienced by subjects undergoing other painful procedures (Johnson, 1973; Leventhal *et al.*, 1979). However, the latter found that the way in which the briefing was phrased was an important variable; words such as 'pain' could cancel the discomfort-reducing effect of the information. The response to drug withdrawal is similarly influenced by the extent of the patient's knowledge of and participation in the withdrawal procedure. Stitzer *et al.* (1982) found that knowledge of the dose reduction schedule serves to reduce symptom complaints, and they suggest that much of the withdrawal symptomatology may be a result of anxiety and uncertainty. These findings, together with those of the present study, suggest that when withdrawing addicts from opiates, providing the individual with information about the sort of intensity of symptoms that might occur could reduce withdrawal distress, but that this issue deserves further investigation.

Seasonal Hypomania in a Patient with Cold Urticaria

N. S. HARVEY and W. I. MIKHAIL

The clinical and biochemical disturbances of a patient with seasonal hypomania and cold urticaria are described and discussed with reference to histamine metabolism in mental disorder.

Allergic disorders have often been reported in association with mental disturbance, although interpreting the relationship is more complex than has often been assumed (Rix *et al*, 1984). Shared biochemical features have been suggested in recent work on the behavioural associations of histamine and antihistamines (Hough & Green, 1984). Histamine acts through two classes of receptors, both of which are affected by antidepressants and neuroleptics (Kanof & Greengard, 1978). Antagonism of the type designated H1 causes sedation, whereas unbalanced antagonism of the H2 type, produced by cimetidine, has been linked with psychiatric manifestations, which are often affective in nature (Crowder & Pate, 1980; Hubain *et al*, 1982; Titus, 1983).

This report describes a case of intermittent cold urticaria, occurring in close relation to unipolar affective disturbances over several years. There are no reports in the literature over the past two decades of any similar case, or of any recognised psychiatric morbidity associated with cold urticaria. It is estimated that about 0.4% of the population are affected by cold urticaria at some time in their lives (Champion *et al*, 1969).

Case History

Presentation of cold urticaria

The patient, a caucasian male born in 1961 first became ill in 1972, when he collapsed after swimming. During each subsequent winter he experienced episodes of diffuse

FIG 1 The chronological relationships of hypomaniac episodes, cold urticaria, and temperature extremes in the patient's area of residence.

swelling affecting his hands and face, often accompanied by headaches, from exposure to the cold.

In 1975 he was examined at St John's Hospital, London where dermatographia and a marked urticarial reaction to ice were noted. The following tests were normal or negative: immune globulin E, cryofibrinogen, cryoglobulins, C_3 and C_4 complement components, serum protein electrophoresis, lupus cells, anti-nuclear factor, rheumatoid factor, Wasserman reaction, and stool microscopy for ova and parasites. A diagnosis of idiopathic cold urticaria was made.

Psychiatric presentation

In the severe winter of 1978, when the episodes of swelling commenced, the patient (then aged 17) began to talk incoherently about electronic forces and of a plan he had to construct a magnetic train. Growing restlessness culminated in a sudden outburst of bizarre excitement, and at psychiatric examination a preoccupation with an electronic activity which fused mind and body was noted. On the day he was admitted to the psychiatric unit, a disturbance arose in which he jumped from one bed to another while stripping off his clothes.

Psychiatric assessment and observation

The patient complained that thoughts were crowding his mind, which tired him and prevented him from achieving his objectives, and that sounds seemed very loud. He heard the incoherent voices of a crowd talking to him and had a vague notion that someone was trying to harm him. His talk was coherent, though circumstantial, and he was markedly distractible. His mood was one of moderate euphoria, with transient feelings of dysphoria and marked irritability. Apart from impairment of concentration, his cognitive functions were intact. No abnormality of pre-morbid personality was elicited. There was a history of a single episode of severe depression in a maternal aunt. On physical examination no significant abnormality was found, but there were scratch marks on his hands and face in keeping with recent urticaria.

During his first week on the ward he was awake for most of the night, when he would bang his head on the wall or

roam about and shout. He climbed chairs and attempted to throw himself on to the floor, likening himself to an Olympic swimmer, and he smashed the glass of a door. During this time he was given a daily dose of 15 mg of trifluoperazine and up to 250 mg of chlorpromazine. He improved gradually during five weeks of in-patient treatment. A diagnosis of mania was made.

A month later, at follow-up, he was doing well and his medicines were reduced. Shortly afterwards he stopped his treatment, and did not return to the clinic because he remained well.

Clinical Course

Dermatological follow-up

The patient's next contact with St John's Hospital was in early 1981, when he was readmitted for further routine tests.

Following the application of an ice cube to his arm, blood samples from the antecubital fossa produced circulating histamine, reaching a maximum level of 9 ng/cm^3 after 14 minutes. He was placed on a cyproheptadine, which he used intermittently.

Psychiatric follow-up

Since the first psychiatric admission the patient has shown annual hypomaniac episodes, occurring only during the winter. His parents noticed that they built up over three or four weeks, after periods of unusually severe exposure to the cold. Although the psychiatric admission was delayed in 1984, it occurred during severe cold weather, when he spent several days working outdoors to repair his car. The onset was preceded by marked urticaria. Fig. 1 shows the chronological relationship between the two conditions.

Discussion

This patient, with proven idiopathic acquired cold urticaria, was manic on presentation and typically hypomaniac during each subsequent psychiatric dis-

turbance; the clinical features were observed and documented by one of us during three of the six episodes recorded here.

The onset of cold urticaria prior to the disturbed behaviour was observed by the patient's parents, who lived with him throughout the period in question. Selective recollection may have affected the accuracy of their observations, although for most occasions examples could be given of everyday activities leading to greater cold exposure just before the disturbances. The parents were not aware of any early affective changes which could have been responsible for increased cold exposure.

In cold urticaria, a massive release of histamine is detected in the circulation (Kaplan & Beaven, 1976) and in the urine (Granerus *et al.*, 1969), which is generally undetectable in other types of urticaria due to its rapid tissue uptake. There has never been substantiation of the view once held that parenteral histamine might benefit man by increasing cerebral blood flow and capillary permeability (Simpson & Kline, 1961). On the contrary, histamine release may correspond with a systemic reaction which includes light-headedness, a sensation of tightness in the chest, transient hypotension, and fainting. These effects may be expected to contribute to any emotional distress associated with cold urticaria, and were reported by our patient in relation to acute episodes, although during in-patient treatment his recorded pulse and blood pressure readings were normal.

Elucidating possible aetiological factors in individual examples of regular cyclical affective disorders is difficult (Jenner & Damas-Mora, 1983). Although our patient's clinical picture could have resulted from the remarkable coincidental concurrence of two independently seasonal conditions, it appears

more likely to be due to provocation of one by the other, or to a shared aetiological factor.

There is evidence to suggest that histamine crosses the blood-brain barrier in animals (Crossland & Mitchell, 1956; Snyder *et al.*, 1964), although this has not been shown in man. Endogenous release of hypothalamic histamine may be markedly increased during cold exposure (Taylor & Snyder, 1971), and its intraventricular injection in rats results in catalepsy and hypothermia (Pilk & Nowak, 1979). Besides histamine there are other products of mast cell degranulation, such as prostaglandin D₂ and the leukotrienes, and one of histamine's metabolites, imidazoleacetic acid, when given parenterally to rats, has been shown to cause increased exploratory behaviour, hyperactivity, ataxia, and catalepsy (Marcus *et al.*, 1971). Increased levels of conjugated imidazoleacetic acid have been found in the urine of schizophrenic patients (Kobayashi & Freeman, 1961).

Finally, the effects of cyproheptadine should be considered. It is the drug of choice for cold urticaria (Wanderer *et al.*, 1977), and has a greater therapeutic effect than other drugs with a more powerful anti-histaminic action, probably due to its influencing the kinin system at tissue level. Cyproheptadine is also a serotonin antagonist, which has encouraged the suggestion that its use might be associated with psychiatric disturbance (Pearce *et al.*, 1977). However, in our case cyproheptadine was only introduced after the first three psychiatric episodes, and it was taken irregularly for subsequent attacks of cold urticaria. The patient's family observed that in the short term the drug exerted a beneficial calming effect on the mood disorder, but it is not known if its overall effect could have been to contribute to the onset of some of the episodes.

Priapism and Psychotropic Medication

J. KOGEORGOS and C. de ALWIS

Priapism is a rare but serious adverse effect of psychotropic drugs resulting from their peripheral alpha-adrenoreceptor blocking action. Two patients developed this during treatment with oral phenothiazines: one was treated surgically with a venous shunt, and the second case resolved after intracavernosal injection of an alpha-adrenoreceptor stimulating drug.

Priapism is a pathologically prolonged and painful penile erection, usually unassociated with sexual desire or intercourse. It is caused by obstruction of the venous drainage from the corpora cavernosa, while that from the corpus spongiosum and glans penis remains unaffected. Priapism, therefore, can be clinically differentiated from a normal erection in that only the corpora cavernosa are turgid, the corpus spongiosum and glans penis being quite flaccid (Wasmer *et al.*, 1981). Prompt diagnosis and treatment are essential, or the resultant stasis will lead to thrombotic changes and ultimately to fibrosis of the corpora cavernosa, and thus to permanent erectile impotence. This can be restored only partially by implantation of a penile prosthesis—a difficult and sometimes unsuccessful operation (Pryor, 1982).

The usual treatment of priapism is surgical, initially involving aspiration and saline irrigation of the corpora cavernosa, the creation of a temporary

fistula between these and the corpus spongiosum and, if the venous drainage is still unsatisfactory, a corpus cavernosum saphenous shunt (Pryor, 1982). Recently, there have been encouraging preliminary results for injection of metaraminol, an alpha-adrenoreceptor stimulating drug, directly into the cavernosal space (Brindley, 1983, 1984; Stanners & Colin-Jones, 1984).

Priapism may occur at any age, being most frequent in the third and fourth decades, and may arise in a wide variety of circumstances; it often occurs on waking, but only occasionally following prolonged sexual stimulation. Some 30-40% of affected cases have the condition recurrently; about half are idiopathic. The remainder are associated with diverse factors, which can be grouped into three main categories: local pathology of the pelvis—a direct obstructive effect; blood dyscrasias, especially sickle cell disease, which facilitate thrombosis by increasing

blood viscosity; and factors, including drugs, which alter the neurological mechanism of normal erection and detumescence.

The main drug groups known to be associated with priapism are anti-hypertensives and anti-coagulants. However, there has been an increasing number of reports recently linking priapism with psychotropic medication. The two patients described here were treated in the same psychiatric unit within two years of each other.

Case reports

Case 1

A 38 year-old journalist with a known history of schizophrenia was admitted following a recurrence of the illness. He had had previous admissions to other hospitals, and treatment with phenothiazines and haloperidol, with no apparent adverse effects; there was no other relevant medical or drug history. On admission he was restless, thought-disordered, deluded, and hallucinating; physical examination and routine blood tests were normal. He was prescribed chlorpromazine (100 mg q.d.s.) and flurazepam (15 mg, nocte, increased to 45 mg, nocte), and gradually improved.

Three weeks after admission he complained of a persistent and painful erection, and was transferred to the urological unit. Aspiration of blood clots from the corpora cavernosa, followed by saline irrigation, were without effect, and a right corporo-saphenous and left bulbo-corporal shunt were created on the following day. His priapism gradually resolved, although he later developed a penile ulceration, which necessitated an in-dwelling catheter for ten days. The priapism was attributed to the chlorpromazine, which was discontinued. In the following four weeks he remained well, but as he subsequently absconded and did not return his long-term outcome remains unknown.

Case 2

A 42-year-old merchant seaman was referred following a suicide attempt. He said he had become increasingly depressed because he was unable to visit his seven year-old daughter, who was in the custody of his estranged wife. He also volunteered a history of chronic alcoholism and extensive abdominal surgery for malignancy, but these claims were later found to be greatly exaggerated, and other statements could not be verified. There was no history of blood dyscrasias or pelvic disease. At the time of admission he was receiving monthly injections of vitamin B12, combined with oral iron, calcium and pancreatic enzymes (Pancorex). Physical examination was normal, except for multiple operative scars on the abdomen. Blood tests showed a mild iron-deficiency anaemia and slightly elevated blood glucose: a glucose tolerance test was consistent with 'dumping syndrome'. Barium meal indicated a Bilroth I gastrectomy.

On admission he was dishevelled but co-operative, and appeared only mildly depressed. He was prescribed chlor-methiazole, (1 g b.d.) in a reducing regime, to which was

added, two days later, promazine (100 mg, nocte). On the fourth night he woke at 4 a.m. with an erection, which persisted and became increasingly painful. He reported this 12 hours later, when a diagnosis of priapism was made. Pethidine (50 mg, i.m.) and Prochlorperazine (12.5 mg i.m.) were given, and he was transferred to a urological hospital, where Doppler ultrasound examination of the penile arteries showed a high flow state, supporting the diagnosis of priapism. Procyclidine (10 mg, i.v.) had no effect, but infusion of metaraminol deep into the cavernous tissue was effective, resulting in the gradual resolution of the priapism. On return to the psychiatric ward, two days later, his penis was still enlarged and tender, but no longer turgid. He was not prescribed any further phenothiazines, and suffered no recurrence of the priapism in the subsequent six weeks. During this period his behaviour changed dramatically, in that he became unreasonable, over-demanding and abusive, thus reinforcing our initial diagnosis of a Munchausen syndrome. His discharge was precipitous, and he did not attend for follow-up.

Discussion

Contrary to popular belief, the excessively prolonged penile erection of priapism, far from being a sign of virility, is in reality a source of distress and embarrassment, and may lead to permanent impotence.

The pathophysiology is unclear. Normal erection results from sustained increase of arterial supply to the erectile tissue, which is probably achieved by relaxation of valves or 'polsters' (Wasmer *et al*, 1981), allowing increased blood flow into the corpora cavernosa, combined with simultaneous regulated partial constriction of 'shunt' arteries, which impedes venous drainage (Wagner *et al*, 1982). These vascular changes are under autonomic nervous control, both sympathetic and parasympathetic/vipergic, the latter depending on a recently identified class of splanchnic fibres, which utilize as a neurotransmitter vasoactive intestinal polypeptides (Polak *et al*, 1981) with atropine resistant vasodilatory responses (Bloom & Edwards, 1980). Preponderance of sympathetic over parasympathetic activation is associated with penile flaccidity, while the reverse results in erection.

Most psychotropic drugs are potent alpha-adrenoreceptor blockers, and could induce priapism by directly inhibiting the sympathetically controlled detumescence, which is probably the result of their peripheral action on those receptors lying within or close to the cavernosal space. Perhaps the strongest evidence for this mechanism comes from Brindley's elegant experiments on both normal men and men with erectile impotence, in whom he was able to induce penile erections by intracavernosal injection of the alpha-blocker phenoxybenzamine, which

were subsequently resolved by a similar injection of the alpha-stimulating drug metaraminol (Brindley, 1983, 1984). The effectiveness of this technique has been further demonstrated by the successful treatment of a patient with priapism secondary to chronic myeloid leukaemia (Stanners & Colin-Jones, 1984), and by the satisfactory treatment of our second patient.

The suggestion that other pharmacological properties of neuroleptic drugs, such as their anticholinergic or hypotensive action, could cause priapism (Meiraz & Fishelovitch, 1969) has not been substantiated. There have been no reports of priapism associated with the use of anticholinergic drugs alone, nor evidence of hypotension in cases of drug-induced priapism, including our two patients.

A wide range of psychotropic drugs have been implicated in priapism (Pryor, 1982; Barnes, 1984), but Mitchell & Popkin (1982) could find only 15 cases of priapism reported in which the drug involved was specifically identified; most frequently this was a phenothiazine, as with our two patients. Six of these patients were taking thioridazine, and seven others chlorpromazine, in one of whom priapism followed a single injection (25 mg, i.m.). One patient was taking thioridazine combined with trifluoperazine, and another was on mesoridazine. Since then, 11 cases have been reported in which priapism was attributed to trazodone—an antidepressant with known alpha-blocking properties (Scher *et al*, 1983).

However, if alpha-adrenergic blockade—a com-

mon property among psychotropic drugs—is the cause of drug-induced priapism, why is the condition apparently rare among psychiatric patients? It may be that in a proportion of cases it goes unrecognised or unreported because of its short duration and spontaneous remission, or because of the obvious difficulties of detecting such a feature in markedly psychotic patients. However, it is more likely that priapism is a complex and multi-factorial disorder, and that the interaction of several factors is necessary for it to become manifest. Possibly, psychotropic drugs induce priapism in only a small proportion of men who are sensitive to alpha-blockade at a critical site, perhaps at the putative valves or polsters (Lawrence *et al*, 1984), and only if additional factors such as cannabis or alcohol are present (Winter, 1981). This could explain the observed inconsistency of response of such men to psychotropic medication, as with our first patient (who had previously been treated with the same drug with no adverse effect) and with the patient reported by Dawson-Butterworth (1969). Our second patient had a long history of alcohol abuse up to the time of his admission.

Psychotropic medication is thus associated with a small but definite risk of priapism, which is increased with the use of phenothiazines and trazodone. Early recognition and prompt treatment are essential to prevent permanent impotence, and will depend on careful history-taking and alertness to known predisposing factors such as blood dyscrasias, especially sickle cell trait, and previous abnormal erections.

Mania Following Bereavement

SIR: The assumption is not uncommonly made in papers that since there have been few reports of a particular event, relationship, etc., in the literature, this means that the phenomenon is rare or uncommon. A case in point is Rosenman and Taylor's case report of mania following bereavement (*Journal*, April, 1986, 148, 468-470). Surely such assumptions are quite erroneous. How many clinical psychiatrists take the trouble to report such cases in the literature? I wonder if there is the slightest connection between cases reported and cases actually occurring.

J. A. G. WATT

Gartnavel Royal Hospital
1055 Great Western Road
Glasgow G12 0XH

SIR: The case report by Dr Rosenman and Ms Taylor (*Journal*, April 1986, 148, 468-70) is further evidence of the continuing difficulty there is in riding modern psychiatry of Freud's erotic fantasies. As Oscar Wilde might have said, the only absurdities tenaciously believed are the really unbelievable ones.

In their discussion, the authors refer to the "paradoxical nature of the response". The false paradox is in their use of the words "grief" and "mania" as opposites. Grief is a normal experience and the opposite might be happiness. The patient was not just happy but described as profligate, grandiose, talking constantly, overbearing and irritable. In a word, manic—an illness, the opposite of which is a state of endogenous depression which itself is not merely grief. Does anyone really expect mania to occur only after weddings?

While one can accept the seemingly jolly clown entertaining everyone while his heart is broken because of his lost love, it is going a bit too far to see the same 'manic defence' in the patient described whose clear bipolar affective vulnerability was shown by the puerperal depression preceeding the manic episode. A non-specific stress reveals a vulnerability (the nub of the matter is that this is metabolic and not primarily psychological) specific to the patient which might, in different individuals, be anything from skin disturbances to cardiac problems. Or was Dr

Rosenman tempted to treat the lady with antidepressants? Freud was very bad on the functional psychoses, unbelievably so.

Gluten Free/Gluten-Load Trial

SIR: I read the paper by Dr Vliissides *et al* (*Journal*, April 1986, 148, 447-452) with interest, and have a few points to make.

The pathophysiological processes in gluten sensitive enteropathy or coeliac disease are totally independent of the pathophysiological processes in schizophrenia. I have raised this because constantly in the literature coeliac disease and schizophrenia are brought nearer to each other during discussion. In gluten sensitive enteropathy improvement in most patients is seen in one month, and one should not expect such dramatic changes in the form of improvement in schizophrenia in a short time, as the pathophysiological processes in causation of their symptoms are not the same.

Removal of glycoprotein gluten from the diet may help to improve symptoms of schizophrenia, but addition of gluten would not necessarily make symptoms worse. If one selects severely ill psychotics, whose symptoms are at a peak, further deterioration in clinical symptoms by addition of gluten to the diet cannot be adequately measured by existing clinical rating scales. One may expect only no change in scores.

Having used gluten free diet and essential fatty acids in the treatment of schizophrenia with some success, I recommend a minimum period of eight to ten months must elapse before the gluten free diet is considered not beneficial. Nutritional therapies generally take a long time to cause any changes in the body. The total period in the above papers was extremely short.

A Unitary View on the Aetiology of Schizophrenia

SIR: The article by Wexler (*Journal*, April 1986, **148**, 357–362) is interesting and thought provoking. It reminds one of the theory of neural plasticity and shows that brain function is dynamic rather than static. I had earlier formulated a hypothesis on the aetiology of schizophrenia, attempting to explain the conflicting findings in schizophrenic research.

Some individuals are genetically determined to have weak and vulnerable dopaminergic systems. When subjected to stresses, part of the dopaminergic pathway ceases to function. To compensate for the loss, the surviving dopaminergic fibres give off additional nerve terminals and D2 receptors. This overreaction gives rise to a relative increase in dopaminergic activity and manifests as the positive symptoms of schizophrenia. In mild cases, the dysfunction is self limiting and dopaminergic transmission is able to restore to its previous level of functioning, and the process is completed. The psychotic episode is thus named a schizophreniform reaction.

In more severe cases, the dysfunction is more chronic and progressive. It results in actual degeneration of the dopaminergic pathways. These degenerative changes are supported by the CT scan studies, postmortem findings, as well as the regional difference in cerebral blood flow and PET studies. The significant reduction of CCK (hippocampus, amygdala), somatostatin (hippocampus), opiate receptors (caudate nucleus), 5 HT receptors (frontal cortex), angiotensin converting enzymes (globus pallidus and substantia nigra) and GABA (nucleus accumbens) also point to this degenerative shrinkage involving certain parts of the brain. Postmortem findings indicated subependymal gliosis in the diencephalon and hypothalamus in chronic schizophrenia. This is consistent with the CT scan evidence of a moderate enlargement of the third and lateral ventricles reported in approximately half of the chronic patients. Gliosis is usually a response to brain injury. The origin of this gliosis may lie at the midbrain ventral tegmental area where the dopaminergic neurones originate. The A10 group of the ventral tegmental area spreads along the mesolimbic and mesocortical pathways to end at the limbic structures and pre-frontal area. Because the DA content in the pre-frontal cortex is only approximately 1% of the DA concentration in the striatum, pathological evidence of cell loss or gliosis in this area may not be obvious. However, cerebral blood flow and PET studies do reveal the frontal region abnormalities.

Negative symptoms seem to result when the degeneration becomes more extensive and when the mesocortical dopamine system is involved. As the

effect of DA antagonist in this system is greatly diminished, the symptoms are irreversible with neuroleptic drugs. It may actually become more prominent when the positive symptoms are under control.

Cerebral lateralisation studies have established the asymmetric distribution of major neurotransmitters in the human brain. Dopaminergic systems are left hemisphere biased. It can be deduced that lesions of the dopaminergic system are reflected as left hemisphere dysfunction and such are found in the CT scan, regional blood flow, PET and EEG studies, as well as a specific increase of dopamine in the left hemisphere.

The reactive compensatory process may not be neurotransmitter specific. Hence an alternation in production of noradrenalin may occur in response to dopamine system degeneration, giving rise to affective symptoms which sometimes occur simultaneously or following schizophrenic systems.

Endogenous Subtype of Depression

SIR: I read with interest the Young *et al* article (*Journal*, March 1986, **148**, 257–267).

Their conclusion rests on their use of the SADS. They interpret SADS item 326 as addressing anhedonia. Rather, this item addresses loss of interest or pleasure. Thus, someone who had lost interest in all activities but nonetheless could still enjoy some activities when actively involved in them would be rated 6 on this item. Thus, this is not strictly a loss of pleasure item and neither anhedonia nor DSM-III melancholia can therefore be accurately inferred.

From a theoretical point of view, Klein (1974) has hypothesized that pervasive anhedonia is the underlying hallmark of melancholia, in contradistinction to decreased interest in activities with retained ability to experience pleasure. From a practical standpoint, many patients report significant and often pervasive loss of interest in activities but still retain the ability to enjoy them once involved. SADS does not allow

for making this distinction, and I believe that collaborative study interviewers did not add additional questions to their interview to cover this distinction. If not, it is then impossible for the authors of this article to convert their SADS interview into a DSM-III diagnosis or to derive a sub-type characterized by pervasive anhedonia.

I submit that perhaps they have identified one group which has pervasive loss of interest without the traditional vegetative signs of depression while another group has pervasive loss of pleasure plus the neuro-vegetative signs, as has already been hypothesized by Klein.

It seems logically impossible for a patient to meet DSM-III criteria for melancholia without meeting at least probable criteria for RDC endogenous depression. Thus, it appears to be a mistake to report 14 patients with DSM-III melancholia who did not also have at least probable RDC endogenous depression.

Reliability of the SRQ-20

SIR: We were interested to read the paper by Drs Mari & Williams (*Journal*, January, 1986, 148, 23-26). We used the SRQ-20 as a screening instrument among in-patients of a general medicine ward at the AIIMS over a six-month period. Using 11 as the cut-off point, we examined (using the ninth edition of the Present State Examination and a detailed psychiatric history) all those scoring 11 or above as well as a systematic sub-sample of those scoring below 10.

Out of a total of 326 administered the SRQ-20, 158 were examined and diagnosis was made on the basis of ICD-9. At the end of the study, specificity and sensitivity were determined at each possible cut-off point from 1 to 20, based on the 42 psychiatric cases and 116 non-cases. A correction factor was applied so as to generalise the results to the whole sample using the method suggested by Goldberg (1978).

We found great divergence between specificity and sensitivity. The original cut-off score of 11 had a sensitivity of 46.6%, and specificity of 74.1%. At 7/8, these were, respectively, 77.4% and 66.6% (sensitivity) and 51.1% and 54.4% (specificity). We found 9

the ideal cut-off, where sensitivity was 62.9% and specificity 62%. Females, and those educated at school level (matric) or less, scored significantly higher ($P < 0.05$ and $P < 0.01$ respectively, using the chi-squared test). The mean score for the total population was also high—7.78 (SD ± 4.95).

We feel, therefore, that the SRQ-20 may need considerable modification for use in known physically ill samples. Weighting certain questions, skewing questions toward the more "psychological", changing "false positive" questions, and defining the duration or severity of symptoms, may all have to be considered.

Monoamine Oxidase Inhibitors

SIR: Professor Blackwell's warning (*Journal*, February, 1986, 143, 216-217) about the danger of minimising the risk of MAO inhibition is welcome, if only as the basis for informed discussion. However, as he will no doubt recall (Samuel & Blackwell, 1968), he himself was not always on the side of the angels.

At Bethlem Royal Hospital, the reaction to Rowe's initial observation, shared by Professor Blackwell, was one of ridicule, while my suggestion that Rowe's observation be taken seriously was treated with contempt. My persistence in pursuing the matter was encouraged only by Professor Linford Rees. It is to the credit of neither of us that this encouragement has never been recorded by Blackwell in any of his many publications, nor in the publication of which I was a joint author (Samuel & Blackwell, 1968). This letter will be the first time in the 23 years since this not altogether unimportant discovery was made, that Professor Rees' essential contribution will have been acknowledged in print. It was my pleasure, in 1983, finally to speak to Rowe. To my astonishment he was totally ignorant of the

sequel to his observation and did not know of his mention in any publication nor in Ayd and Blackwell's (1970) book, *Discoveries in Biological Psychiatry*.

I suspect that Professor Blackwell is once again suffering from 'cryptoamnesia', this time in his reference to "manufacturers' myopic files". In the 1970s, such files were part of his responsibility, when working for a "manufacturer", and if 'myopic' who should be blamed? However, such a situation is not true in the 1980s, here in the UK. In 1963, medical advisers in the pharmaceutical industry felt it was their job to push reports of adverse reactions aside ("it would be premature and unscientific to warn patients not to eat cheese": Weber, 1963). Today, all serious side-effects have to be recorded within 48 hours of notification to the company. We no longer shoot the messenger.

On Serious Violence During Sleep-Walking

SIR: Ian Oswald and John Evans in their article (*Journal*, 1985, 147, 688-691) added important information to our knowledge about violence during sleep. Other sleep disorders, in addition to somnambulism (Podolsky, 1958) can also generate violent behaviour (Raschka, 1984). The term "sleep-related dangerousness" introduced by Moldofsky appears useful. Such behaviour can include car accidents related to narcolepsy and assaultive behaviour related to sleep drunkenness. The criminological and forensic implications of the latter were discussed by Bonkalo (1974). Sleep disorders generating sleep-related dangerousness are often influenced by drug intake including alcohol. The resulting behaviour is often preventable.

Book Reviews

When Luck Runs Out: Help for Compulsive Gamblers and Their Families. By Robert Custer and Harry Milt. Oxford: Facts on File Publications. 1985. Pp. 239, £10.95.

This book, set very much in the American gambling scene, might be dismissed as inappropriate to the British reader. This is not the case because the problems it describes have their counterparts in this country. Legalised gambling and gaming has been available in a much more widespread form in Britain since the introduction of the Betting & Gaming Act 1960. In the way that where problems with alcohol are related to the availability of drinking so problems with gambling are related to the freedom with which gambling can occur amongst the population as a whole. Many members of society enjoy gambling as a pastime and recreation. They would object strongly to it being controlled or removed from their range of activities. The evidence is that rigorous control diverts gambling from legal to illegal participation and is therefore no solution to the problems of the few who become as dependent on gambling as others are dependent on alcohol. The Royal Commission on Gambling 1978 referred to this problem but felt that no recommendations could be made concerning any control since the size of the problem was not known but in any case was probably small. It offered the well worn cliché that more research is needed and did however recommend the setting up of a National Council on Gambling as one way of investigating the extent of the problem.

When Luck Runs Out describes vividly typical stories of compulsive gamblers. It gives a number of personal histories describing the effect on the individual, on the family and by implication on society. The authors bravely describe the personality and psychopathology of the compulsive gambler but recognise that while the traits and upbringing they describe may be common they are by no means universal. They do try to set out the typical picture of the individual but perhaps more important they describe those features by which the compulsive or pathological gambler may be recognised. So often, family doctors, social workers, psychiatrists, and probation officers recognise that there is a family problem, presenting perhaps as depression in the spouse, money shortages, disturbances in the children but not enquiring about the

possible cause; equally the family may be reluctant to divulge what is the hedonistic and unacceptable explanation of their problem.

A further chapter sets out the action which must be taken by the member of the family who identifies problems. Hopefully it will be the gambler who would recognise the difficulties and seek help. Much more commonly it will be the spouse and occasionally it will be the business associate who has been defrauded or otherwise put into financial difficulties who notices the problem and decides to take action. The role of Gamblers Anonymous and its related organisation Gam-Anon is seen as the cornerstone of treatment but brief mention is made of a psychotherapeutic approach linked with a referral to GA.

This book is a useful addition to the sparse literature on compulsive gambling and can be recommended to psychiatrists, social workers, probation officers, community psychiatric nurses and others whose lack of information about this syndrome may result in them overlooking the possibility of helping someone who is in need.

C. P. SEAGER, *Professor of Psychiatry, Northern General Hospital, Sheffield*

From Research to Clinical Practice: The Implications of Social and Developmental Research for Psychotherapy. Edited by George Stricker and Robert H. Keisner. New York: Plenum. 1985. Pp. 457. \$45.00.

Psychotherapy and research are uneasy, and at present controversial, acquaintances. The recent repetition of old, unproductive debates has highlighted the need for a new partnership. This book points to a more fertile mating by extending the notion of psychotherapy research to explore, as its subtitle suggests, the implications for psychotherapy of research in social and developmental psychology.

The book's editors attempt to show how knowledge of psychology research can refine the clinical practice of psychodynamic psychotherapy. In twenty invited chapters, relevant aspects of social psychology (eg leadership, non-verbal behaviour, aggression, and attitude change) and developmental psychology (eg infant and childhood development, gender role development, adolescence, and mid-life

change) are explored, and then a number of special topics examined (eg fantasy, religious experience, and psycho-linguistics).

As is inevitable in a multi-authored text, the contributions are variable in style and clarity. Each chapter concludes with a summary of general implications for practice, though these differ markedly in originality and applicability. More problematic is the discrepancy between the task and the essential belief system of some authors who attempt to write about psychodynamic application while resorting to narrow psychological principles. For example, Worchel and Worchel write about "aggression and psychodynamic therapy" from an essentially behavioural standpoint, without reference to Melanie Klein's work and with only passing reference to the important contributions of Kernberg to the elucidation of the central role of aggressive dynamics in much common character pathology.

I was more impressed by the application of research in developmental psychology, and in particular by Bloom-Feshbach's chapter on early childhood development. Here they relate research on child-rearing styles to attachment theory, illuminating the controversial debate about the importance of the therapist's warmth and empathy; and also elucidate some of the distinctive features and implications of the child's relationship with each parent.

Also of interest to me was the chapter by Nachmani on "psycho-linguistics and psycho-pathology" in which fundamental linguistic concepts are used to illuminate the contributions of Winnicott, Bion and Meltzer to the explanation of schizoid pathology, which is seen as a result of the disruption of a capacity to organise thought and express it through language.

There is something in this book then for every practising psychotherapist, as well as for those psychiatrists who are concerned with the role of psychological and social factors in generating and treating psychological disorder. The book should be available in all libraries, and is worth dipping into repeatedly.

MIKE HOBBS, *Consultant Psychotherapist,
Warneford Hospital, Oxford*

The Politics of Mental Health. By Ragnhild Banton, Paul Clifford, Stephen Frosh, Julian Lousada and Joanna Rosenthal, Basingstoke: Macmillan. 1985. Pp. 202. £20.00 (hb), £6.95 (pb).

Some twenty years ago, as a revitalised post-war psychiatry diffused outwards from its old asylum

base, it was met by the shrill voice of anti-psychiatry which in its various forms succeeded in condemning most aspects of psychiatric practice. Although anti-psychiatry is no longer so fashionable there remains a constant trickle of literature which attempts to build upon and extend the old critiques. This book is one of the latest and like its predecessors is a curious amalgam of insight, naivety and contradiction.

The analysis of contemporary mental illness develops along several interesting lines which seem to show the strong influence of Foucault. The authors, for instance, argue explicitly for a Foucaultian notion of power as coming from "below" (because it is a characteristic and product of all interactions) rather than power from above which simply reflects the dominance of one person or groups over another. They also adopt a social constructivist position with regard to the individual. Past critiques of psychiatry have stressed that mental illness is, in a sense, "constructed" by its social recognition and labelling; these authors employ parallel arguments to show that the individual, who is the focus of psychiatric intervention, has no essential or universal nature, but is similarly constructed in social interaction. And thirdly, they present a critique of the "community" which even in progressive psychiatry is usually little more than an idealised and romanticised "community remembered".

This critique might easily have led to a nihilist account of all psychiatry but these authors, all individual "mental health workers", outline an alternative radical therapeutic practice. In this scenario, however, much of the preceding critical analysis is somehow turned on its head. Thus the operation of power in its more traditional form of race, gender and class, it is argued, must be opposed. To be able to do this radical therapists apparently must themselves first be analysed: the authors regret that the new revolutionaries will have to fork out a lot of money for this in the capitalist market-place but such is the price of radicalism. These psycho-analytic skills—gained at such expense—would then be deployed in a community mental health programme, albeit a radical one which presumably ignores the fact that the "community" is itself a social construction of medicine over the last thirty years.

At a time when, apparently, "the forces of reaction threaten to wreck all vestiges of humane living" we are invited to join a "struggle that can contribute to the resistance against this upsurge in oppressiveness". Thus the therapist must enhance "subjectification" and replace silence with speech through intensive supervision of their clients: para-

doxically, in a world where humane living is so precarious there may be nothing more oppressive than this.

DAVID ARMSTRONG, *Senior Lecturer in Sociology, Guy's Hospital, London*

Depression in Multidisciplinary Perspective. Edited by Alfred Dean. New York: Brunner/Mazel. 1985. Pp. 245. \$27.50.

Despite increasing public subscription to the proposition that understanding depression requires a multifactorial approach, we all find difficulty in emerging from our particular corners to a mid-field viewing point and there is thus a continuing need for volumes such as this which make a panacea of the multidisciplinary perspective. Editing such collections however is not easy in the absence of more than a small number of really interdisciplinary studies. Volumes usually consist of a series of disparate contributions extolling the particular viewpoint from each corner—genetic studies, life events, personality characteristics and biological markers—barely welded together by the editor's introductory and concluding chapters. Alfred Dean avoids repeating this pattern, and has produced a book well worth adding to any collection of earlier such volumes. Issues involving treatment and diagnosis are given as much attention as aetiology and avoid the partisan flavour which occasionally, if unintentionally, accompanies the specialist contributions of experts from one special field. Even the chapter devoted specifically to cognitive behavioural treatments covers a whole range of such approaches, including the rather "less familiar" self-control methods of Rehm and colleagues; [and in outlining the theoretical rationale for these treatments it makes up for the rather hurried coverage of internal psychological resources by the editor's initial chapter on the epidemiology of depression]. One chapter gives a balanced discussion of the possible value of laboratory tests as a guide to prescribing—for example the DST is considered a better guide to length than to type of treatment. A similar caution about the DST emerges in other chapters, particularly in the one devoted to depression in the elderly where the difficulty of the diagnostic distinction between depression and dementia is discussed in detail (the DST has been found to relate to both, but computed tomography may help weed out the "pseudodementia's"). Diagnostic and treatment issues in childhood depression are given a similar thorough examination with similar conclusions: "ageism" at both extremes of the life course may

have exaggerated the degree to which affective disorders here differ from those found in the midrange of adulthood.

The section on psychosocial etiology has the merit of presenting studies with a relatively wide, if not completely multidisciplinary, range of variables, among them the editor's and his colleague's Albany-Troy-Schenectady prospective study. In all the standard simple combination of variables life-stress and support is supplemented by other factors such as mastery, personal competence, self-esteem, physical illness or life stage]. Furthermore the editor's own choice of the measure of "strong-tie social support" gives rise to a sensitive discussion of that area. However, some rather crucial issues seemed to be glossed over: one is the difficulty of establishing the time order of all these factors even in a longitudinal study. Little attention is paid to the need to exclude all with a depression whose onset predates the beginning of the study period, to cover life-stresses occurring right up to the time immediately before onset and to ensure that measures of psychological resources do not postdate (and thus possibly result from) such an onset. Moreover their use of the continuous CES-D score (instead of a cut-off at 16) is strangely at odds with some of the other contributions in the volume's diagnostic sections which stress the importance of distinguishing depressive symptoms from clinical caseness. A further issue—that life-changes as such predict depression less well than *undesirable* life events—only emerges sideways. Perhaps this is because the refinement of measures of different types of life events, and the findings concerning the predictive role of loss experiences, have tended to occur more on this side of the Atlantic—just another reminder of how many more multidisciplinary volumes we still need. But meanwhile this is a great help along the way, particularly in the fine lists of recent references which follow each chapter.

TIRREL HARRIS, *Department of Social Policy and Social Science, Royal Holloway and Bedford New College, University of London*

The Psychology of Schizophrenia. By John Cutting. Edinburgh: Churchill Livingstone. 1985. Pp. 475. £40.00.

In this book the author has bravely attempted to cover almost all the work ever done on the psychology of schizophrenia. His assumption seems to be that by presenting all this work (the fundamental facts as it were) in one place from an unbiased viewpoint a clear picture will emerge as to the true nature and cause of schizophrenia. I believe that this

"bottom-up" approach is misguided and has led to a disappointing book.

The first problem lies with the organisation of the material. Although the author speaks highly of the cognitive approach adopted in much recent research, he has chosen a very much older framework so that his chapters are divided into the faculties memory, attention, perception and so on. Much of the material he reviews sits uncomfortably on the boundaries of these categories. For example, Broadbent's 1958 filter model on which much schizophrenia research is based, attempts to explain *common* aspects of attention, memory and perception.

The second problem lies with the selection of the material. With so much to be covered in so little space the author has to be selective in what he reports. Given his neutral standpoint, however, he has no criteria for deciding which is the most important aspect of each study. Every reader is bound to disagree with some of the author's selections although for different reasons. To take just one example, Goldberg *et al* (1981) are quoted in relation to the "alien hand sign", but their conclusion that this is due to unilateral frontal rather than corpus callosum lesions is not mentioned.

The third problem lies with the lack of an overall structure for the conclusions from the various sections. There are many details in this book which are fascinating and well worth reading, but they do not add up to a coherent story. For example the author suggests that first rank symptoms have been over-emphasised in the definition of acute schizophrenia, and also that chronic schizophrenia should be treated as a separate entity. Even if they are incorrect, these ideas could have been used with advantage in discussing other aspects of research, but the author has not systematically adopted such a framework.

The author's final conclusion is that acute schizophrenia is due to some unspecified, but relatively discrete brain damage (labelled "hemisphere imbalance") whereas chronic schizophrenia is caused by some unspecified, but more generalised brain damage. It is not at clear to me how these disorders of the brain relate to the symptoms of schizophrenia or to the results of the hundreds of psychological experiments reviewed.

I believe the author could have written a much better book if he had used a "top-down" approach, reviewing the literature from some definite and biased viewpoint. Furthermore since his book is entitled the psychology of schizophrenia I would have expected the final conclusions to be in terms of psychology rather than the brain. It is perfectly possible to understand schizophrenia or any other mental illness in terms of some psychological deficit

without specifying the underlying damage to the brain. In the case of schizophrenia such specification is premature and cannot be derived solely from psychological studies.

CHRIS FRITH, *MRC Senior Scientist, Clinical Research Centre, Harrow*

The Social Science Encyclopaedia. Edited by Adam Kuper and Jessica Kuper. London: Routledge & Kegan Paul. 1985. Pp. 916. £29.95.

I've never actually read an encyclopaedia before, preferring to keep it for my desert island. Nor, of course, can anyone actually read through an encyclopaedia from Abnormal Psychology to Wilhelm Wundt, not at least with understanding or authority. However, I found myself carried along by this stimulating and interesting book; it is lovely to get away from the tunnel vision of one's professional reading.

I took my samples from areas I know reasonably well, from areas I know a bit and would like to know more, and from areas I have always found difficult (phenomenology, sociobiology and Piaget, for example). The many biographies complement the articles and make compelling reading—even about people one didn't particularly wish to know about! Rather like the compulsive qualities of a Radio Three talk, listened to by accident during the concert interval.

Five hundred contributors from 25 countries provide 700 entries: the editors must be superpersons! The major social sciences—anthropology, economics, political science, political theory, psychology and sociology—have master entries of immense learning; good examples of the perennial lure for academics to compose outstanding essays to put in relatively obscure places. None more so than Ralf Dahrendorf's "Social Science", a 1500 word essay of breathtaking scope, scholasticism and coruscating intellectuality.

If you are middle-aged and intellectually burned out or young and looking for something different I can thoroughly recommend this book. Not, unfortunately, for the psychiatry, whose entries are banal and poorly informed (schizophrenia, suicide, neuroses, ECT, for example). One can only wonder how they could be composed let alone accepted. However, of the areas closest, psychology and sociology are excellently done. One persistent impression is the abiding influence on the core social sciences of Karl Marx. The entry: "Marx's theory of history and society" is fascinating and one wonders how it is that his impact on psychiatry—even social and community psychiatry—has been minimal.

So, while one cannot have resource to the book reviewer's perennial recommendation "for the departmental library", this is certainly a book for the family library: interesting, clear, well printed and bound, and for these days not over-priced.

SIDNEY CROWN, *Consultant Psychiatrist, The London Hospital*

Mental Handicap: A Multi-Disciplinary Approach.

Edited by Michael Craft, Joan Bicknell and Sheila Hollins. London. Baillière Tindall. Pp. 421. £30.00.

This outstanding book consists of a series of essays by a team of experts involved in practical provision for the mentally handicapped. In her introduction, Professor Joan Bicknell refers to the book as a successor to Tredgold's classic text. This may be so in that the publishers are the same and that this bids fair to become the standard text on the subject. But this new work, as Professor Bicknell says, reflects an entirely fresh approach. Public and professional opinion has undergone a U-turn in regard to intellectual handicap since Tredgold's time. One aspect of this change of course, as Professor Bicknell points out, is reflected in the choice of a multi-disciplinary team to write this book instead of relying on the "medical model" as previously.

Tredgold was an enthusiastic original member of the Eugenics Society, believing in Morel's doctrine of national degeneration, as modified by Mott and others. In 1909 he warned that, in relation to mental defect, the chief evil was that of "propagation". It was eugenic concern of this kind which in part led to the very restrictive Mental Deficiency Act of 1913 and to the steep increase in institutional population of the mentally handicapped which followed the First World War.

In contrast to these attitudes is the commitment of all the writers in the present volume to community care and the sympathetic and helpful chapter on 'Sexuality and Personal Relationships' by Ann and Michael Craft. Malcolm Johnson, in his chapter on 'Social Policy and Service Development' refers briefly to the epidemiology of mental handicap, mentioning the paucity of reliable statistics and difficulty of definition; though there is more agreement about the more severely mentally handicapped. It seems that the effect on prevalence of better life expectation may be balanced by prevention. Michael Craft in his chapter on "Classification, Criteria, Epidemiology and Causation" deals more fully with incidence and prevalence, pointing out that, even in the well defined entity of Down's syndrome, the situation is not clear. Offsetting

increased life expectation is a reduced incidence due mainly to lowering of maternal age, associated with more frequent termination of pregnancy in older women on grounds of age. Craft points to the limitations of assessment in the mildly retarded, particularly when used as a prognosis for future intellectual development.

Each chapter in this book is clearly written and the editors are to be congratulated on the success of their efforts. The presentation is appropriate for students in all the disciplines involved and the text is suitable for reference.

Malcolm Johnson, writing from his chair at the Open University, points to an obvious shortcoming in the present service when he regrets the lack of any informal care network to link different agencies and units. He says that money is not enough, but he might equally have said "There is not enough money", for he names a succession of ministers who have failed to deliver the goods.

BRIAN KIRMAN, *Formerly Consultant Psychiatrist, Queen Mary's Hospital for Children, Surrey*

Overcoming Resistance: Rational Emotive Therapy with Difficult Clients. By ALBERT ELLIS. New York: Springer Publishing. 1985 Pp 228. \$21.60.

Ellis is the originator of Rational-Emotive Therapy (RET), one of the earliest approaches to cognitive behaviour therapy and this book is devoted to the question of resistance in therapy. Although the book is addressed mainly to RET practitioners, it contains sufficient background information to be comprehensible to therapists of other orientations.

The many forms in which resistance may be encountered are examined in detail. A distinction is made between "normal" resistance, which can be expected to occur frequently as an intrinsic part of the process of changing, and other types of resistance which require special attention if therapy is to be successful. Ellis concentrates on resistance by patients with more serious disturbances such as borderline personalities and alcoholics. He offers an array of techniques and practical suggestions, with numerous examples from his extensive clinical experience. These range from the forceful methods which are characteristic of RET, to the more gently persuasive methods advocated by cognitive therapists such as Meichenbaum. Of particular interest is the discussion of ways in which the therapist himself may cause or contribute to the patient's resistance, and how this may be tackled.

One negative aspect is in the book's presentation. There is a considerable amount of repetition and self-congratulation in Ellis's style of writing which readers may find off-putting. In spite of this, however, the book deserves attention for its useful contribution to this important but neglected topic.

ANNE GODDARD, *Lecturer in Clinical Psychology, The London Hospital Medical College*

Secure Provision: A Review of Special Services for the Mentally Ill and Mentally Handicapped in England and Wales. Edited by LARRY GOSTIN. London: Tavistock. 1985. Pp. 318. £14.00 (hb), £7.95 (pb).

This book is divided into four parts: a history of the development of secure provisions, services, the law, and a discussion of concepts of dangerousness and social control.

The issues covered are relevant not only to forensic psychiatrists but also to general psychiatrists. Faulk argues that much of the anxiety felt by general psychiatrists about the care of the 'dangerous' patient is due to lack of contact with them. Special Hospitals are covered by Hamilton in the second part of the book; particularly worrying is the increasing difficulty found in transferring patients from Special Hospitals, the average period of time to wait now being several years.

Professor Gunn outlines five fundamental problems within the prison medical service: recruitment and training, compulsory treatment of mentally abnormal offenders, the production of court reports, widespread prejudice towards doctors who practise in this setting and the ethical conflicts this creates in the doctor, and finally the ever increasing number of individuals the prison medical service is required to deal with.

Regional secure units developed largely in response to the 'yawning gap' between secure Special Hospitals at one extreme and the NHS hospitals at the other, which have been identified by the Butler and later Glancy Reports. The historical development and current state of regional secure units are discussed by Professor Bluglass, and current practice in these units by Treaseden, who shows how they have narrowed but not yet completely closed the aforementioned gap. The legalistic approach towards psychiatric practice is adopted by Hoggett in part three of the book. I shall largely gloss over this section, which I felt was overly technical and legalistic with a distinctly 'thou shalt not' tone. It was with relief, then, to turn to Bowden's entertaining exposition on issues in which dogmatism and certainty have little place, i.e. what is dangerousness?, the relationship between mental disorder and dangerousness, the relationship between victim and offender, and questioning whether forensic psychiatrists are aspiring to an expertise that in reality they do not possess. In a somewhat disturbing but constantly engrossing and thought-provoking final essay, Bean argues that secure provision for mental patients are the mirror image of the prison in the legal system. The view of psychiatrists as agents of social control is a role which most psychiatrists are reluctant to acknowledge. However, it is perhaps a responsibility that should not be shed away from. Control can be less damaging ultimately to the patient than a policy of radical non-intervention, allowing the patient to "die with their rights on", which the legal approach threatens to create. (From penal/legal systems). . . "they will always be on the welfare of their patients, rather than, say, a strict demand for legal justice".

GILLIAN MEZEY, Registrar, The Maudsley Hospital, London

Sleep and its Disorders. By J. D. PARKES. Eastbourne: Holt-Saunders. 1985. Pp. 499. £29.50.

Sleep because it is a universal experience rarely fails to fascinate the reader, and its disorders often present difficult diagnostic and treatment problems. Hence the immediate appeal of a new book on the subject. It is part of a series on *Major Problems in Neurology* edited by Sir John Walton. This volume is by a single author who has a wide experience in the field, both from a practical and research point of view, and can thus be expected to offer an up-to-date perceptive view, which is amply fulfilled. The chapters are grouped into three main sections, "Normal Sleep", "Sleep Disorders" and "Pharmacology and Sleep", each in a wealth of detail with ample bibliography. The first, occupying one third of the book, provides an account of normal sleep and its variants, its anatomico-physiological basis, and the relationship between circadian rhythms and sleep. Each is divided by many side headings providing helpful pointers, particularly for the reader wishing to gain access to the text from the valuable index.

The comprehensiveness is emphasised for example by sub-sections on shiftwork, jet lag and hormones in relation to sleep, again sub-divided. The chapter on parasomnias covers a wide range of topics such as sleep myoclonus, sleep paralysis, and sleep walking where historical asides, an account of the phenomena and possible treatment are given. Some may feel that the text is skimpy in parts, including those on psychiatric matters, but appropriate references are given when amplification is required. The chapters on daytime sleepiness and sleep apnoea furnish the expected range of views enlivened by historical allusions and useful tabulations, characteristic of much of the book, as well as illustrations, some in colour. The treatment section on the use of hypnotics and stimulants is somewhat disappointing, though there are comprehensive listings, an overall perspective does not emerge. Somewhat disappointing also is the abrupt end of the book, after a section on the treatment of cataplexy. A final chapter on where research is leading, what new insights on sleep apnoea are likely to emerge, for example in relation to cot deaths, would greatly enhance the book, which is otherwise recommended both for the general and specialist reader.

D. F. SCOTT, Section of Neurological Sciences, The London Hospital

Recovery from Schizophrenia: Psychiatry and Political Economy. By RICHARD WARNER. London: Routledge & Kegan Paul. 1985. Pp. 380. £25.00.

"To render schizophrenia benign we may, in essence, have to restructure western society." The last sentence of this book suggests a political polemic but it is much more than this. As well as a useful and comprehensive review of such familiar areas as problems of diagnosis, prevalence, treatment and prognosis, the reader is urged to consider schizophrenia in a broader context than that of the traditional clinical and family approach. The author's central theme is of the hitherto undervalued contribution of

"political economy" in the production and perpetuation of schizophrenia.

The author identifies a link between unemployment and adverse outcome of schizophrenia. He also speculates that the competitive pressures of working in an industrial society may be inimical for a recovering schizophrenic, while a role in a non-industrial community based on subsistence needs is less demanding and more appropriate. This may contribute to the better outcome of schizophrenia in developing countries where it is also facilitated by the lack of stigma and alienation endured by the schizophrenic and his relatives in the West. The author also believes that upper class individuals in the Third World are more at risk of the illness but, as industrialisation approaches, this social class gradient switches round to conform to the pattern familiar in the West.

An important debate which is aired concerns the place of antipsychotic medication. The argument is put forward that, while such drugs have value in management, the outcome of schizophrenia has not improved since their introduction. Deinstitutionalization in Britain began before they appeared and was largely due to social therapies and the stimulus given to rehabilitation by the labour shortage after the war. Medication is considered to be unnecessary in a significant proportion of patients and to increase the risk of relapse in drug-withdrawn patients. The concern is expressed that antipsychotic drugs have, in some community care programmes, been used as alternatives rather than adjuncts to psychosocial care.

The author writes with passion and concern in a highly readable and stimulating way and the reader is challenged to clarify his own views about schizophrenia in the course of a highly recommended read.

ALAN KERR, *Consultant Psychiatrist, St Nicholas Hospital, Newcastle upon Tyne*

Bisexualities: Theory and Research. Edited by FRITZ KLEIN and TIMOTHY J. WOLF. New York: The Haworth Press 1985. Pp. 255. \$24.95 (hb), \$16.95 (pb).

A new liberation movement has just started. Another sexual minority group are desperately looking for an identity: the bisexuals. Rejected by heterosexuals for being a threat to monogamy and persecuted by homosexuals for sitting on the fence and not admitting to their homosexuality, they are closing their ranks and encouraging each other to "come out of the closet" and announce their bisexuality. Little wonder that this book has far more politics than science. It challenges many sexual dogmas and questions some of the widely accepted views on what is considered 'natural'. It does so, very convincingly at times, very passionately always, but with very little serious research to back up its claims. The book does, however, give some interesting statistics: 10-15% of the population are bisexuals, there are thirty to forty million bisexuals in the USA, 10% of married males also participate in some homosexual activity and 18% of males demonstrate as much homosexual as heterosexual behaviour during their lives.

For many people, including some professionals, bisexuality is nothing more than a gender confusion or psychological hermaphroditism. If you accept the statistics quoted above and the results of some of the research papers published in the book (one of them had a sample of 18 cases), you will have no difficulty in accepting some of their conclusions. You will accept that 'bisexuals are not rare, only rarely identified', 'bisexuality is the norm, exhaustive homo or heterosexuals are moved away from the norm by cultural conditioning', that 'bisexuality can be life enhancing... can facilitate marital adjustment' and will even believe that bisexuals are lucky because they 'can enjoy the best of two worlds'.

Whatever you think of these conclusions, one thing is certain, they will make you doubt some of the widely held beliefs about what is considered by the majority as 'normal'.

The book ends by an account of the growing bisexual organisations in New York, San Francisco and Chicago and an exhaustive bibliography of 400 references on bisexuality.

This book can be an eye-opener for those who feel uncomfortable with non-traditional sexual behaviour, has little practical value for the general psychiatrist, but can be an important source for those who are actively involved in gay counselling or working with other sexual minority groups.

WAGUIH R. GUIRGUIS, *Consultant Psychiatrist, Psychosexual Clinic, St Clements Hospital, Ipswich*

Spheres of Group Analysis. Edited by T. E. LEAR. London: Group-Analytic Society. 1985. Pp. 141. £5.50.

In the preface to this short but readable account of group analytic psychotherapy in practice, the editor acknowledged our debt to the teaching of S.H. Foulkes. This book is like a group analytic group. The individual contributors include an educationalist, a social scientist, a chaplain, a nurse, and several psychiatrists whose fields of practice are as diverse as alcoholism and sexual deviancy. Each chapter is interesting and worthwhile in its own right, but together they are more than the sum of the individual's experience. They are united by a common theoretical approach, stressing the potential of the group to value and strengthen the unique contribution of each individual.

The initial chapters provide a theoretical perspective which is complemented by others on large groups and uses in a family therapy setting. Multi-author books are often weakened by their diversity of style and content. In this case the diversity only demonstrates the broad ranging applicability of the group analytic approach.

This book will be useful for students on the Institute training courses but also can be expected to appeal to a much wider general audience.

I. F. MACILWAIN, *Consultant Psychiatrist, Netherne/St George's Hospital, London*

Alcohol and Aggression. Edited by PAUL F. BRAIN. London: Croom Helm. 1985. Pp. 228. £22.50.

"The Drunkard, in his drunkenness, killeth his friend, revileth his lover, discloseth secrets and regardeth no man." The Elizabethan author of the *Anatomie of Abuses* might not have believed that by 1985 to attribute aggressive behaviour to alcohol might be seen as distorted thinking generated by 19th century capitalists' desires (couched as the Temperance Movement) for greater worker discipline. He might also have been surprised on reading this impressive compilation that even the explosion of 20th century science still leaves the question of whether alcohol increases aggression as a matter of if and but.

Even if he could not quite follow studies of alcohol-related changes in latency of cats' quiet biting attacks, or the Convict Cichlid's response to male conspecifics, or the influence of alcohol on GABA receptors, testosterone levels and nerve cell membranes, he would be impressed at the breadth of physiological, behavioural and pharmacological research reviewed here. Both he and a 20th century psychiatrist might regret that more human individual and clinical data could not be included. How do drunken assaults unfold? The epidemiological and sociocultural view of the association between alcohol and interpersonal violence, though well covered, leads to a slight weighting of the evidence in favour of drunkenness as an excuse for wife beating (for example) rather than wife beating being a result of drunkenness.

Dr Brain is at pains to point out that aggression is a complex notion and covers a wide range of behaviours. In the same animal, alcohol may increase one type of aggressive behaviour and decrease another, and the effects may be reversed as dosage changes. Ethological studies hold promise. For example, it has been possible to show that alcohol increases aggressive behaviours in submissive monkeys and dogs in the group, but not in the dominant monkey. Interestingly, if the dominant male monkey becomes intoxicated there is a relaxing of social restraints—a phenomenon for study at the medical staff dinner? But we are warned of the risks of extrapolation. Contributors Berry and Smoothy quote P. G. Wodehouse. "No more alcohol for me," said Buffy. "Look what it does to the common earth worm." "But you are not a common earth worm," I said, putting my finger on the flaw in his argument right away.

JONATHAN CHICK, *Consultant Psychiatrist, Royal Edinburgh Hospital*

The Culture-Bound Syndromes: Folk Illnesses of Psychiatric and Anthropological Interest. Edited by RONALD C. SMONS and CHARLES C. HUGHES. Dordrecht, The Netherlands: D Reidel. 1985. Pp. 516. £54.25, US\$69 00, Dfl. 195.00.

The contributors to this volume on folk illness are psychiatrists, sociologists and anthropologists. Much of the bizarre behaviour described, albeit shaped by the cultural background in which it occurs, may be found in any psychiatric text-book but difficulties arise when attempts are made to categorise culture-bound disorders in accordance

with western nosology. Although it is true that none of the three versions of the Diagnostic and Statistical Manual of Mental Disorders of the American Psychiatric Association can conceptually accommodate the syndromes described, I suspect that if there were a third world equivalent of the DSM-III similar difficulties in classification would arise with disorders familiar to western psychiatry. Ethnocentric bias in medicine probably correlates well with levels of misunderstanding elsewhere. It says a great deal for the combined wisdom of the editors (one a psychiatrist and the other an anthropologist) that this problem is addressed and in many instances resolved. Unfortunately there are occasions when emphasis on semantics blurs rather than clarifies meaning.

When modern diagnostic criteria and methods are available, folk beliefs and supernatural explanations for them fade. They can then be understood more readily in neurophysiological and biological terms. One example is *old hag*, a syndrome described in a small hitherto isolated community in Newfoundland and characterised by a paralysis of arms and legs with hallucinations. It became easier for the diagnosis of sleep paralysis to be made after a road was built yielding access to a medical centre.

Hysterical phenomena and psychotic behaviour are frequently found in connection with the culture-bound syndromes. It seems highly likely that media influences shape and spread disturbed behaviour. Indeed *amok*, a violent psychosis peculiar to the Malays, may be difficult to distinguish from mass murder carried out by those whose personality deficits are exaggerated by chemical intoxication. Indiscriminate terrorism reminiscent of *amok* and based on group expectations has already been exported to international airports. *Koro* or the genital retraction syndrome appears as a 'neurotic' epidemic in South East Asia, but it would be interesting to speculate what would bring the universal fear of the shrinking penis to the surface of Western man.

The strength of this volume lies in its understated plea for the transcultural understanding needed in our multi-ethnic society. I would strongly recommend it to all psychiatrists working with minority groups.

DENNIS FRIEDMAN, *Medical Director, Nightingale BUPA Hospital, London*

Emotions, Cognition and Behaviour. Edited by CARROLL E. IZARD, JEROME KAGAN, and ROBERT B. ZAJONC

Noting the recent and dramatic growth in the school of cognitive psychology, the editors felt that this trend should be paralleled by a similar emphasis on emotional and social development. Hence the need for this book, which arose from a series of American discussion groups on child psychology. Eighteen chapters describe recent empirical and theoretical work aimed at furthering our understanding of the relationship between emotion and cognition in the developing child.

Particularly interesting among the theoretical issues are chapters on the interaction of emotion and thought in the development of empathy, the distinction between attributing failure to lack of effort (leading to guilt) or to others

(leading to anger), and the relevance of good versus poor imagery in the development of phobias. Other interesting chapters present evidence that the frontal region of the left hemisphere is concerned with pleasant emotions, that an abundance of positive emotions facilitates the development of altruism, and that hypnotically induced emotion can influence learning and memory.

There is a wealth of important material in this book, but it is difficult to find, being hidden in some very long and detailed accounts of research. The editors provide an introductory chapter which is little more than a non-evaluative overview. It would have helped to give more of a commentary on each chapter, drawing attention to the highlights or, at least, to have drawn together the important advances in a concluding chapter. Because this has not been done, my impression is that few people will take the trouble to sift carefully through this book which can reveal some fascinating insights into the ways that children develop

DAVID K. B. NIAS, *Senior Psychologist, Darenth Park Hospital, Kent*

Theory and Treatment of Anorexia Nervosa and Bulimia: Biomedical, Sociocultural, and Psychological Perspectives. Edited by STEVEN WILEY EMMETT. New York: Brunner/Mazel. 1985. Pp. 332. \$30.00.

This is an American compilation issue. It consists of 17 chapters by authors of a wide variety of professional backgrounds put together by a minister of the church who is also a psychotherapist specialising in the treatment of eating disorders. The volume is divided into three sections which cover biomedical, sociocultural and psychological perspectives of anorexia nervosa and bulimia followed by a concluding section.

The quality is very uneven and mixed. Some chapters, notably those by Spack on Medical Complications of Anorexia Nervosa and Bulimia and the one by Copeland on Neuroendocrine Aspects of Eating Disorders, provide detailed and comprehensive reviews of the literature in these areas. Others are much more personal and reflect the viewpoint of the author, for example, Orbach's interesting chapter giving a feminist perspective of anorexia nervosa and White Jr.'s chapter on intervention strategies and outcome considerations give synopses of their work.

The book contains a great deal of information but unfortunately it is not presented in an orderly way and therefore does not hang well together. A fundamental fault is the failure to provide definitions for the terms 'anorexia nervosa' and 'bulimia' and it is by no means certain that each author utilises the same diagnostic criteria. Indeed, several chapters do not attempt to distinguish these conditions.

Although the label bulimia nervosa was originally coined to describe a variant of anorexia nervosa, the diagnosis has established itself as a distinct disorder. Some patients have a past history of anorexia nervosa and others do not. There still remains considerable confusion and uncertainty concerning the most appropriate diagnostic label to attach to those patients who have suffered from anorexia nervosa and who binge and vomit, especially if

their weight approaches the average range. It is therefore of the greatest importance to clarify the diagnostic criteria in respect of bulimia nervosa and anorexia nervosa if the results of research in these areas are to produce fruitful distinctions. Unfortunately this book has fudged this clarification of such a fundamental issue although it contains a range of interesting perspectives.

EDWARD STONEHILL, *Consultant Psychiatrist, Central Middlesex Hospital, London*

Literature and Medicine. Vol. 4. Psychiatry and Literature.

By PETER W. GRAHAM. Baltimore, Maryland: Johns Hopkins University Press. 1985. Pp. 173. Subscription: \$12.95 (individual), \$25.00 (institutions).

"Our criticisms, from age to age, reflect the things that the age demands". The application of T. S. Eliot's dictum to this collection suggests a demand for rather stodgy fare.

This volume consists of a series of disparate essays, on the broad theme of the connection between psychiatry and literature; and in particular between "madness" and authorship. It gets off to a bad start with a contribution by Thomas Szasz, the originator of 'Conventional Western Psychiatry'—the good commercial guys wearing pale hats and the bad institutional guys wearing dark ones. The bullets duly whistle past and through the dummies stuffed with false antitheses, but no real blood is drawn and our hero, I fear, will live to make many more 'B' movies.

There follow several studies of individual authors: Holderlin, Ezra Pound, Hayden Carruth, Hilda Doolittle and Mary Kempe. In so far as they bring out some obscure authors for occasional inspection, these essays are valuable, but they are written in the solemn Eng. Lit. style, as if Academe was breathing in the vast thick pants of expiring PhD theses. There is the occasional stimulus of disagreement. The essay on Pound quotes one of his beautiful and allusive translations of oriental lyrics—*The Jewel Stairs' Grievance*. It is condensed and impressionistic. The critic concludes, from the fact that 'it refuses to advertise its meaning', that 'it is a poem of and for a paranoid mind'. Well really! This clumsy Malleus Poetorum would strike down a whole bookshelf of poets, including our own genial Will Shakespeare himself.

J. L. T. BIRLEY, *Consultant Psychiatrist, The Maudsley Hospital, London*

Mind and Body: The Psychology of Physical Illness. By STEPHEN A. GREEN. Washington: American Psychiatric Press. 1985. Pp. 205. \$22.50.

The author's aim is commendable: "Proper medical treatment requires an understanding of what illness means to a particular individual at a particular time in his life. This . . . requires listening to patients and understanding what they communicate in words and by their silence. This book is designed as a framework for achieving such an understanding." Central to the approach adopted by Dr Green is his belief that abnormal psychological responses occur when the patient is unable to grieve effectively the losses incurred by ill-health. That theme is discussed at length. In

the remainder of the book, common responses to major physical illness are described and the concept of "illness dynamics" is outlined.

Of interest are those chapters in which the author presents extracts from his psychotherapeutic interviews with patients whose psychological responses to a variety of physical illnesses include denial, anxiety, anger, depression and helplessness. On reading these *verbatim* extracts, one gets a strong impression of the author's genuine warmth, empathy and considerable clinical skills.

Less satisfactory are Dr Green's excursions into theory and the advice he proffers regarding therapy. In the theoretical discussions, readers will look in vain for clearly stated, refutable hypotheses derived from factual observations. Instead, psychoanalytically based insights are presented with an air of certainty which belies the flimsy anecdotal evidence upon which they depend. Moreover, these insights are not merely harmless flights of fancy; Dr Green is convinced that, for at least some medically ill patients, what is required is "a relentless probing of unconscious material". The mind boggles. In your reviewer's opinion, patients suffering from serious physical illness require relentless probing of their unconscious like a hole in the head.

STEVEN GREER, *Reader in Psychological Medicine, King's College Hospital, London*

Principles of Behavioural Neurology. By M-MARSEL MASULAM. Philadelphia: F. A. Davis. 1985. Pp. 405. \$68.75

This volume is one of the much valued black volumes in the Contemporary Neurology series, the Editor-in-Chief of which is Fred Plum. Other useful volumes of interest to psychiatrists in the series have included "Management of Head Injuries", edited by Jennett and Teasdale, and "Mental Retardation and Related Disorders", edited by Charles Barlow.

The present volume is certainly a worthy member of the series, and gathers together chapters by distinguished authors on a variety of topics in what might be termed "higher mental function", which no longer find an easy home in texts of either neurology or psychiatry. However, the enormous territory to be covered leads to rather skimpy treatment of some important areas. For example, a neurologist or a psychiatrist who wishes to know more about the current thinking of those with a special interest in memory might well do better to go to some paperback written for the general reader with an interest in this subject.

A useful chapter is from the Editor, Dr M-Marsel Masulam, on the phenomenon of attention. It is intriguing, to say the least, that the performance of patients with unilateral neglect of space to the left can be improved by financial reward. This is a good example of the central theme of the book—attempts to understand the integration of the behaviour, unseen cognitive processes and feelings of the individual with his disordered brain.

In his preface, the Editor reassures psychiatrists that there is no inexorable movement towards reclassifying all

psychiatric diseases within the realm of neurology. He writes that, for the vast majority of patients who seek psychiatric help, a neurological approach is no more useful, or desirable, than a chemical analysis of the ink would be for deciphering the meaning of a message. However, new discoveries on the cerebral organisation of emotion and personality are prompting the inclusion of neurological causes into the differential diagnosis of many conditions that have traditionally been attributed to idiopathic psychiatric disorders.

ANTHONY HOPKINS, *Physician in Charge, Department of Neurology, St Bartholomew's Hospital, London*

Mental Health Care in the European Community. Edited by STEEN P. MANGEN. London: Croom Helm. 1985. Pp. 278. £16.95.

Steen Mangen has compiled an account of the mental health policies of the (then) nine countries of the Common Market. The authors, who come from different mental health disciplines, are often natives of the countries whose policies they describe. The editor contributes a most interesting introductory survey of the European scene and chapters on the United Kingdom and Germany. Some of the other chapters are less well written, although Professor Stromgren's chapter on Denmark is particularly interesting and readable. The book is produced in camera-ready form and there are too many typographical errors.

In spite of its multilingual origins, the English is generally good.

Although we have shed some of our traditional insularity we still know little of the social policies which influence the work and the remuneration of our European colleagues. Those who take the NHS, the Mental Health Acts and the declining populations of mental hospitals for granted, will be interested, perhaps surprised, to read of the complicated insurance systems, archaic mental health legislation and the hospital provision of other countries.

This book, like travel itself, broadens our outlook and in some ways it is a book for the specialist the general reader will find much to interest him. Everyone should read Steen Mangen's excellent introductory chapter.

DOUGLAS BENNETT, *Emeritus Physician, Bethlem Royal and Maudsley Hospitals*

Textbook of Child Neurology. 3rd edition. By JOHN H. MENKES. Philadelphia: Lea & Febiger. 1985. Pp. 827. \$64.25.

This is the third edition of a well-established textbook of *Child Neurology* first published in 1974. Chapters are organised predominantly according to aetiology, for example hereditary degenerative diseases, chromosome anomalies, toxic and nutritional disorders and tumours of the nervous system, with a final chapter by Kinsbourne on disorders of mental development. Presentation is systematic for specific disorders covering pathology, clinical manifestations, diagnosis and treatment. Typography layout and production are good.

Since the last edition there has been significant updating in relation to new diagnostic procedures and syndromes, and there is a newly added chapter on neurological manifestations of systemic disease.

Throughout, this text is probably stronger on pathology than clinical descriptions or treatment. For clinical descriptions of hereditary disorders psychiatrists may find other more liberally and appropriately illustrated, and more clinically focused texts more useful. With regard to treatment there is almost no mention of genetic counselling (it is not even indexed) and nothing about the impact of a handicapped or chronically ill child on his family. This is regrettable. Furthermore there is remarkably little mention of associated emotional and behavioural disorders and their treatment even in Kinsbourne's chapter. This final chapter on disorders of mental development is in many respects balanced but noticeably more illuminating in the author's areas of special interest: learning disorders and hyperactivity. There are fewer up-to-date references on for example infantile autism and malnutrition. Curiously absent is an emphasis on the relevance of a broad-based child psychiatric assessment in learning disability and hyperactivity.

A. D. COX, *Senior Lecturer in Child Psychiatry, Institute of Psychiatry, London*

Treatment of the Borderline Personality. By PATRICIA M. CHATHAM. New York: Jason Aronson. 1985. Pp. 585. \$40.00.

It won't be long before we need a guide book not only to borderline states but to books on borderline states. It does actually seem that the more books we have and the fatter they are, the more diffuse and vague the conclusions will be.

Many of these volumes are serious and helpful but it is seldom that they add anything new. This particular book, like many of the others, is by a clinical psychologist in America and has many of the virtues of the systematic thinking in which American universities excel. The author describes the borderline patient from the point of view of object relations theory as understood by Kernberg and people influenced by him. There is quite a lot of emphasis on developmental theory, especially that of Margaret Mahler, and some account of Kohut's theories and their relevance.

It is interesting to examine the index to get some idea of the author's sources of influence. Sigmund Freud is mentioned nine times, Anna Freud four times, and Melanie Klein ten times. Of more modern writers Winnicott is mentioned eighteen times, Bion four times, Rosenfeld three times and Balint three times. On the other hand, Kohut is mentioned fifty-five times, Masterson ninety-three times, Rinsley one hundred and forty-two times, and Kernberg two hundred and nineteen times. This seems a strange emphasis to an English psychoanalyst but I think is probably entirely typical of current American thinking.

It would be easy to be unfair to this book, and if it were the only one of its kind I think it would be quite useful.

Unfortunately there are so many similar ones that it would be difficult to justify spending forty dollars. And even if you did, I am not sure you would know when to apply supportive psychotherapy leading to intensive psychotherapy or supportive confrontative psychotherapy. The Americans think we are very unsystematic, but I find it a relief to simply think of psychoanalytic psychotherapy which we try to apply even with difficult patients. If we take care over the setting and rely on co-operation and help from psychiatrists, social workers and other colleagues, I think many patients can be helped without the need to subdivide the types of therapy we employ.

JOHN STEINER, *Consultant Psychotherapist, The Tavistock Clinic, London*

Eating Disorders: Prevalence and Treatment. Edited by S. W. TOUYZ and P. J. V. BEUMONT. Sidney: Williams & Wilkins 1985. Pp. 160. £24.

This book is based on a symposium on eating disorders held at the University of Sydney. The contributors, with one exception, work in Australia and come from a variety of disciplines, although the overall emphasis of the book is psychiatric/psychological.

The first section is on anorexia nervosa and includes a useful chapter by Touyz and Beumont which describes in detail a "comprehensive, multidisciplinary" approach to management. A relatively novel feature of this approach is a more "lenient" behavioural programme in which patients have greater control over the refeeding process. The programme was as effective as more conventional programmes in terms of weight gain and also was associated with higher patient motivation and was more economical in terms of nursing care. Other chapters consider general aspects of the disorder, nutritional counselling and criteria for recovery.

The second section on bulimia includes chapters on prevalence and classification. In terms of treatment, Suzanne Abraham and colleagues favour a flexible "eclectic" approach and Gail Huon presents some preliminary information on "therapy at a distance", i.e. by mail, with particular emphasis on help-seeking, compliance and drop-out.

The final section on obesity covers epidemiology, the metabolic basis, the effectiveness of psychological treatments and the psychological factors in current surgical procedures. There is an interesting chapter by John Collins on a careful appraisal of the use of hypnosis, which produced encouraging improvement both in terms of weight loss and in terms of psychological factors such as body image and body concern. The book is well written with a nice combination of research evidence and practical advice on management.

Its principal drawback, however, is its price. Even at today's prices, £24 for a 160 page paperback seems excessive.

ERIC BUTTON, *Lecturer in Clinical Psychology, Royal South Hants Hospital, Southampton*

Psychotherapy and the Terrorised Patient. Edited by E. MARK STERN. New York: The Haworth Press. 1985. Pp. 116. \$16.95.

The thirteen brief contributions to this book (mainly by clinical psychologists in private practice) are also published as Vol 4, No. 1. (Summer, 1985) of "The Psychotherapy Patient". The book reads like one of those meals which comprise a series of small dishes. Each contributor says what he/she wants to say, then stops. Though the editor, in the first two contributions, sets out precisely to define the term 'terrorised', most of the succeeding contributors adopt a fairly liberal interpretation: which is all to the good, since it enables them to develop their own idiosyncratic themes.

Mahrer *et al* echo a long felt conviction of my own that to force the patient, in the initial session, into the role of information provider is to suffocate him. It is implied that therapists impose restraints upon patients in order to stay in control. Gagnon confesses "I think I was frightened of losing control of my own emotions and it was frightening for me, therefore, to see others lose control of theirs". Tirnauer develops the idea of the defensive use of power by therapists, although he also stresses that "there are times when a psychotherapist needs to be very aggressive and insistent". At the same time Virginia Fraser Stern cautions that the terrorised patient will just pull away if the therapist is too active.

I was especially impressed by Ellis's account of the six fears "that lie at the very heart of us" and intrigued by Wapnick's proposal that the purpose of therapy is "to offer our patients the healing love of God through our forgiveness of them". In similar vein Dublin, referring to a young musician who lost all who were dear to him in an earthquake avows "I will love the hell out of him". He also brought a patient flowers.

I found this a heartening and inspiring book.

JOHN BIRCHNELL, *Scientific Officer and Honorary Senior Lecturer, MRC Social Psychiatry Unit, Institute of Psychiatry, London*

Ministering to Minds Diseased. A History of Psychiatric Treatment. WILFRED LLEWELYN JONES, London: Heinemann Medical. 1983. Pp. 157. £7.50.

Psychiatry, insofar as it can be differentiated at all from medicine in general, has a relatively brief history. Nevertheless, English scholars, particularly in relatively recent years, have written treatises on various aspects of psychiatric history, the most fecund period being the late 18th and the 19th century.

Dr Wilfred Llewelyn Jones is a good example. He offers us in this slim volume a history of psychiatric treatment which, as he explains in the preface, is designed not only for psychiatrists in training, but for all who work in, or who are interested in the field, not excluding patients and their families.

Dr Jones succeeds in what he sets out to do, and he does so by virtue of his command of the subject and the clarity of his writing. An additional bonus are the several well

chosen illustrations, all of them beautifully reproduced.

If there is fault to be found, it is that Dr Jones attempts to include too much material in too little space. Even so, for those really interested, the book may serve to wet the appetite and encourage further reading.

HENRY R. ROLLIN, *Emeritus Consultant Psychiatrist, Horton Hospital, Surrey*

Disadvantaged Post-Adolescents: Approaches to Education and Rehabilitation. By REUVEN KOHEN-RAZ. New York: Gordon & Breach. 1983. Pp. 224. \$37.50.

This book is the first of a series on 'Special Aspects of Education'. The term 'post-adolescent' refers to the age group extending from the mid teens. Part I contains a discussion of the psychodynamics of adolescence, which is not as thorough as readers of this *Journal* might wish, but nevertheless leads quite naturally to Part II, in which models of normal and abnormal mental development at adolescence are considered alongside problems of the school curriculum. Part III consists of accounts of schemes which have been developed in Israel with the object of achieving at least some measure of educational rehabilitation of disadvantaged post-adolescents. The relevance of these programmes for the UK is not considered.

The central theme of the book is that substantial progress can be made in the education of disadvantaged youth, but that this depends on the development of special educational programmes based on careful analysis of exactly how it is that disadvantage creates the social, emotional and cognitive deficits which an orthodox curriculum merely reinforces. The arguments for this point of view are not perhaps entirely novel, but they are worth studying in the convincing form in which they are presented here. There is not much discussion of the particular educational difficulties of the psychiatrically disturbed adolescent, although these are by no means discounted by the author. The book is not essential reading for psychiatrists; those with a particular concern for this age group, however, will find it thought-provoking.

HUGH G. MORTON, *Consultant Child & Adolescent Psychiatrist, Ninewells Teaching Hospital and Medical School, Dundee*

Towards a Whole Society: Collected Papers on Aspects of Mental Health. Edited by RUTH TERRINGTON. London: Richmond Fellowship Press. 1985. Pp. 176. £5.00.

Thomas Szasz, Maxwell Jones, Ronald Laing, Anthony Clare, Metropolitan Anthony of Sourozh, Kay Carmichael and Robert Gosling, chaired by Elly Jansen: what a start for the Richmond Fellowship's Jubilee celebration book!

The subsequent discussions, which Clare is rumoured to have won, seem minor oscillations about Szasz' position. The section will interest anyone wishing to grasp how discussion on what psychiatrists should do is secondary to the conclusion that they should be. This is illustrated by Dr Malekpour's question to Szasz: what should he do with the

suicidal melancholic? The tentative answer was further questions: who really made who come to whom and why, who made whom the expert arbiter, off which hooks does who let whom off by being a psychiatrist defending concepts of illness, which issues in society are avoided, etc. etc. Szasz, though, pessimistically conceded that people won't give up the concept of mental illness, so psychiatrists will treat them. Without a clear definition Clare seemed to assert that doctors (psychiatrists) should listen to Szasz but must limit themselves as doctors to treating (mental) diseases. All agreed many problems are nevertheless political and religious and over-medicalised.

Sections two and three on Community Care Elly Jansen introduces by confessing that psychiatrists are useful when radical because they alone have special power in the Realpolitik to change their own dominating role. Mosher's favourable summary of the Italian experiment follows, then there is a very human piece by Jean Vanier on L'Arche, and a shrill appeal from the backstreets of Scotland by Jimmy Boyle facing up, to humbug spoken about and done for heroin addicts.

This little book continues by packing in many more easily read, overtly sociopolitical and Antipodean comments on community care. It all represents a well-deserved and well-organised tribute to Elly Jansen and the Richmond Fellowship for a quarter of a century's contribution to the theory and practice of something ill-demarcated but closely related conceptually to psychiatry. For this area the Fellowship clearly remains an important forum for debates, as well as a refuge for our clients.

F. A. JENNER, *Professor of Psychiatry, University of Sheffield*

The Misuse of Alcohol, Crucial Issues in Dependence, Treatment and Prevention. Edited by NICK HEATHER, IAN ROBERTSON AND PHIL DAVIES on Behalf of the New Directions in the Study of Alcohol Group. London: Croom Helm. 1985. Pp. 284. £19.95.

Anyone who travels the circuit of alcohol conferences will know the authors of this book and be familiar with their views. They may be Members of the New Directions Group and hopefully they will have bought a copy of this book. If they have not they should get a copy immediately.

For those of us who don't travel the circuit or who are new to it, like me, then this book is a must. The New Directions Group consists of individuals involved in treatment, education or research in the area of alcohol use and misuse. The Group has no particular axe to grind but is at the forefront of exploring new ideas about alcohol. These new ideas are reflected in the three themes in the book: changes in how we understand harmful drinking behaviour ('dependence'); changes in our confidence that drinking behaviour can be effectively modified in the traditional context of treatment; and changes in our understanding of the effective prevention of harmful drinking.

The first section, on dependence, does not provide any answers. However, it gives us plenty of information and diverse views so that we can make up our own minds about the usefulness of the 'alcohol dependence syndrome'.

Is it theoretically sound, or is it the 'disease theory of alcoholism' in a new guise?

The second section, on treatment, is a bit repetitive, with authors from different backgrounds saying much the same thing. The message, however, is clear. Before we can answer the question as to whether or not treatment works we need to understand the client's needs and we need an analysis of the therapist-client relationship.

The third section on prevention is the most important and the clearest part of the book. The public health approach to the prevention of alcohol problems is succinctly argued by Bill Saunders. The mess of recent Health Education Council Campaigns concerning alcohol and the lessons to be learnt are honestly described by Anthony Thorley.

Alan Maynard completes his chapter on economic measures in preventing drinking problems by quoting from Mao Tse-Tung: 'Complacency is the enemy of study. We cannot really learn anything until we rid ourselves of complacency. Our attitude towards ourselves should be "to be insatiable in learning" and towards others "to be tireless in teaching"'. This book goes a long way in following Mao Tse-Tung's advice.

PETER ANDERSON, *General Practitioner and Senior Registrar in Community Medicine, Oxfordshire Health Authority*

Child and Adolescent Psychopharmacology. By MAGDA CAMPBELL, WAYNE H. GREEN and STEPHEN I. DEUTSCH. London: Sage Publications. 1985. Pp. 167. £19.75 (hb), £10.00 (pb).

The prescription of medication in the treatment of psychiatric disorders in children and adolescents is a considered decision and seldom made in isolation from other therapeutic interventions. It is a pity, therefore, that this book, the second volume of six in a series on Developmental Clinical Psychology and Psychiatry, concentrates solely on psychopharmacology rather than the broader issue of the place of medication in comprehensive treatment programmes. It appears that this was not in the author's brief and they accept this limitation in their work.

The main body of the book consists of five chapters, each devoted to a particular drug or class of drugs. The authors build up the case for the use of medication, in particular diagnoses, by reviewing a large number of studies. I was pleased to see that the case in favour is balanced, in each chapter, by discussion of the contraindications and untoward effects. The first chapter of the book provides a useful introduction to the field with a description of aspects of research methodology giving emphasis to those issues particularly relevant to the field of child and adolescent psychiatry.

The authors achieve the goals they were set. The fact that the subject matter concerns only one therapeutic option reduces the clinical usefulness of the volume. However, the interested reader could make use of the book as a reference source on child and adolescent psychopharmacology.

PAUL A. CAWTHRON, *Registrar, Drug Dependence Unit, Maudsley Hospital, London*

Developmental Theory and Clinical Process. By FRED PINE.
London: Yale University Press. 1985. Pp. 269. £25.00.

In 1975 Margaret Mahler published her major work *The Psychological Birth of the Infant*, it delineated the progress from the stage of a symbiosis with the mother at the age of nine months to that of psychological individuation by the middle of the third year. Now one of her co-authors, Fred Pine, has continued the story in his own book which combines psychological observation, theory and analytic practice. His description of himself as a quiet radical and a flexible conservative is apt.

Four foci may be seen in the development of analytic thought since Freud began his pioneering work. Initially Freud's dynamic theory was based upon the satisfaction of drive instincts which were later subsumed in his theory of ego functioning. The next generations of analysts explored in turn the nature of object-relations and the development of the self. Pine does not accord pride of place to any one of these foci but argues that for each, the individual develops his own, necessary psychology. In an interesting corrective to the over-emphasis on trauma in much analytic literature, he stresses and gives examples of the importance of quiet pleasure and moments of intense experience in child development. In the second half of the book, Pine relates developmental process to clinical intervention. Winnicottian holding and Kohutian mirroring both contribute to the development of a stable self-experience, low keyed pleasure serves as a foundation for a joyous mother-child relationship. In one therapy conducted by the author, being unconditionally available at a set hour for a patient whose approach always turned into flight was of equal importance to the exploration of her conflicts. In this, Pine follows Redl and suggests that the developmental perspective allows the therapist to make specific interventions when faced with deficient functioning.

While the text is wordy and technical, the content is of considerable interest. The volume provides a broad, contemporary view of psychological development and therapy for psychoanalytic practitioners.

MARK AVELINE, *Consultant Psychotherapist, St Ann's Hospital, Nottingham*

Treating the Oedipal Patient in Brief Psychotherapy.
Edited by ALTHEA J. HORNER. New York: Jason Aronson. 1985. Pp. 246. \$25.00.

This book presents the work of an American brief psychotherapy clinical and research project. It is in the form of a series of chapters by different members of the project setting out to cover aspects of theory, patient selection, therapeutic technique, follow up and evaluation. I found the account mostly superficial and lacking in rigour of approach.

The "oedipal patients" treated are described as non-seriously ill, intelligent, psychologically minded, well motivated and with strong egos. In addition they present with a circumscribed area of complaint which can be interpreted in terms of the oedipus complex defined as the wishes, fears and frustrations associated with the opposite

and same sex parents. Any "non-oedipal" issues which might be present must be such that they can be ignored. Their method of patient selection in fact seemed very non-specific and rested on excluding disturbed patients and ascertaining whether patients were prepared to work on an "oedipal focus". There was no examination of the theoretical or clinical validity of creating such an "oedipal focus".

The psychotherapeutic technique used follows the approaches of Sifneos and of Davanloo. The therapist is active and confrontative in "relentless pursuit of even minor resistances in the patient" and in maintaining the so-called oedipal focus and the emotional tension of the therapy. The description of technique is illustrated by vignettes from sessions, but there was very limited explanation of how the examples given did justify the points made. Perhaps they were unconvincing because of the very activity of the therapist. Again theoretical questions did not seem adequately discussed. For example this "activity" of the therapist may preclude certain kinds of activity on the part of the patient. An apparently inactive therapist may be very busy listening to and thinking about what the patient brings and what is happening between him and the patient which holds within it a respect for the patient and a profound challenge to him to take himself seriously. The here and now of the experience and the emphasis on the patient creating his own answers would be considered by some the matrix for change in psychotherapy. From other perspectives there has been interesting work on locus of control in relation to therapeutic change and "pupil" participation in relation to lasting learning. However these and many other issues are not touched upon, and no theoretical justification of the approach is offered. In addition there is no data or significant description of follow-up and evaluation. Instead the reader is offered a rather irritating polemic in which the therapy presented is described with words like courage, enthusiasm and excitement in contrast to a version of classical technique which seemed based on misconception more than anything else.

The therapy presented lacks many features which could be considered essential or particular to a psychoanalytical approach. It is described as having a cognitive flavour but seems without the systematisation of approach offered in cognitive therapy itself. It is impossible to evaluate from the information given in the book and there is little theoretical justification offered for its basic postulates.

KATE DUFTON, *Senior Registrar, Claybury Hospital, Essex*

Counselling in Rehabilitation. By WILLIAM STEWART
Beckenham, Kent: Croom Helm 1985. Pp. 315. £10.95.

This book is aimed at wide readership of therapists and others engaged in the rehabilitation of disabled people. It describes the 'Wessex Model' of individual counselling which promotes self-awareness and insight, combined with a problem-solving approach, and it also highlights the differences, as well as the similarities, in the application of this model to rehabilitation practice. Some of the moral and ethical problems inherent in the process of rehabilitation are briefly considered, and some of the psychological aspects of pain, stress in surgery and sensory loss

are discussed. The book also pays welcome attention to the impact of disability on the family and to the relatives' role within the rehabilitation programme. Brief case reports are used to illustrate some of the issues.

The structure of the book is somewhat confusing: stigma, which concerns all disabilities, is discussed in the chapter on sensory loss; a fairly lengthy account of the clinical picture of rheumatoid arthritis is given in the chapter on pain. Moreover, the whole is marred by occasional repetitiveness and a certain lack of selectivity: lists of aetiological factors of depression and of symptoms of multiple sclerosis are hardly relevant. On the other hand, a mention of other models of counselling would have been appropriate. The book also virtually ignores the field of psychiatric disabilities—a serious omission. Although it would be useful for personnel involved in the rehabilitation of the physically disabled, it is not recommended for psychiatric libraries.

MOUNIR EKDAWI, *Consultant Psychiatrist, Netherne Rehabilitation Service, Surrey*

Recent Advances in Alcohol and Drug Problems Vol. 8

Edited by REGINALD G. SMART, HOWARD D. CAPPELL, FREDERICK B. GLASER, YEDY ISRAEL, HAROLD KALANT, ROBERT E. POPHAM, WOLFGANG SCHMIDT and EDWARD M. SELLERS. New York: Plenum. 1984. Pp. 333. \$49.50.

The eighth volume in this series presents a collection of varied papers of interest to research workers and clinicians in the field of drug and alcohol dependence. Some earlier volumes concentrated on particular aspects, but as the editors make clear volume 8 is a more varied selection of recently published research. All of the articles are interesting and provoke speculation which is relevant to clinical practice, albeit of more specific concern in some instances to the research worker. Thus the first paper by Lars Terenius on the Role of Receptors and Endorphins in Opiate Tolerance and Dependence confirms for the clinician the extreme complexity of the endorphin system; emphasizes the existence of large numbers of biologically active neuropeptides; alludes to inter-species differences; in passing mentions the lack of cross-tolerance between drugs with slightly different receptor profiles; and generally provokes considerable speculation regarding the specific role of drug effects within that complex phenomena known as drug addiction, which the medically qualified member of the multidisciplinary team is responsible for representing to colleagues. This article alone is important. Articles on alcohol self-administration by animals and the genetics of alcoholism in relation to human and animal studies again emphasizes the complexities of the possible interactions involved between environment and genetics. Supported by over 200 references this article states "it is crucial that the scientific community educate the lay public that inheritance does not account for all risk factors, and that the providers of alcohol treatment not over-interpret the current evidence to the point of claiming that all forms of alcoholism are inherited, leaving no room for the importance of environmental conditions. Many individuals with no known genetic predisposition become alcoholic, whereas

even more individuals with strong genetic predisposition do not become alcoholic." In Britain this sound observation must be borne in mind during political and economic discussions where there are considerable forces with a vested interest in the concept that only a minority of individuals are at risk of developing alcohol problems, thereby avoiding the need for general public health measures and education. These are only the first two of 11 excellent contributions reviewing physical consequences of alcohol consumption; analysis of the methodology of studying alcohol-related road accidents; the importance of prospective studies in understanding aetiology; the problems of measuring alcohol consumption in research studies; and a paper by Barry Brown of the National Institute on Drug Abuse regarding treatment issues in non-opiate dependency which is highly relevant to clinicians responsible for establishing drug dependence services in the light of the Government's offer of certain funding for this purpose and the need to achieve a proper balance between opiate and non-opiate dependence.

As with previous volumes in this series, this book is an essential addition to the professional library of any Health District which purports to be providing any service in alcohol or drug problems.

MARTIN MITCHESON, *Consultant Psychiatrist, County Hospital, Hereford*

Video Violence and Children. Edited by GEOFFREY BARLOW and ALISON HILL. Sevenoaks, Kent: Hodder & Stoughton. 1985. Pp. 182. £8.95, £4.95 (pb).

This book represents the final report of an informal working party looking into the influence of watching violent video films on children's lives. The book is multi-author and consists of a series of surveys and clinical reports compiled by members of the working party from different professional disciplines.

Two general population surveys are reported which indicate the extensive number of households which now contain a video. In the National Viewers Survey of 4500 school children, some 50% of households contained a video and in the NSPCC survey of 722 children, some 30% had a video in their homes. Both of these surveys also indicated that somewhere between a half and two thirds of the children in both of these samples had seen one or more videos considered to be violent. Some of these videos have undergone prosecution under the Obscene Publications Act of 1959. These chapters are followed by three Professional Surveys indicating the influence psychiatrists and paediatricians consider violent videos have had on the problems children present in clinical work. The overall opinion is that video nasties may exert an adverse influence on child development and on the development of symptoms. Anecdotal case studies from child psychiatrists further indicate that at the very least the potential detrimental influence of videos on child mental health cannot be ignored.

This demonstrates the large numbers of videos in people's homes exposing children to a wide range of new visual phenomena, including the video nasty. The data

presented make important and illuminating reading. The design and methodology of the surveys makes it difficult to draw firm substantive conclusions concerning the mechanisms by which video nasties may be influencing children; however, the potential adverse influence described emphasises the need for further research in this area.

Overall the book is easy to read and stays within its brief of reporting the findings of its working group. The conclusions are reasonable, as is its price. It is important for professionals involved in child health care to be aware of the potential issues raised in this publication.

I. M. GOODYER, *Senior Lecturer in Child & Adolescent Psychiatry, Royal Manchester Children's Hospital*

Definition of Suicide. By EDWIN SHNEIDMAN. New York: Wiley-Interscience. Pp. 256. \$26.50.

Despite its title, this book is more about understanding than defining. It offers a distillation of old and current views and brings together several approaches, extending from cosmology, systems theory and the American novel to psychoanalysis, logic and psychology. With its 26 chapters aptly arranged from A to Z, this personal account of a well-known suicidologist and Thanatologist transmits an unmistakable air of closure. Obviously, there is a definition too. Taken from its historic origins, the word "suicide" reaches our "current Western world" as a sort of "multidimensional malaise" to become a "self-induced annihilation" for those individuals who, having first "defined an issue" view this act as "the best solution" to their predicament. For nearly every word in his four line formal definition there is an "explication and exegesis".

Of particular interest to workers in mental health is Shneidman's list of "ten common characteristics". Selected on idiographic rather than nomothetic criteria, as the author himself frankly admits, these characteristics have an appealing ring of truth and convey a direct message for suicide prevention. The common stimulus for suicide, he says, is "unbearable pain": reduce it; its common stressor "frustrated needs": fill them; its common purpose "to solve a problem": suggest better and more viable solutions instead, its common goal to "cease consciousness": indicate other aims as clear alternatives; its common emotion depression and helplessness: inject hope, chemically or otherwise; its common internal attitude "ambivalence": exploit it to gain time; its common cognitive set "constricted" vision: open it up for other options to come in view; its common message to others "communication of intent": make sure you hear the message and open the channels to pass it on; its common action "escape": if you have to, keep the exits blocked; its common consistency is with a "life-long coping pattern": activate a positive attitude and draw upon the person's earlier and more constructive coping style.

In this context, suicide prevention calls for a joint effort from all possible angles. Shneidman's choice is a rather grand "Therapeutic Council" in which he will have "a biologically oriented psychiatrist, a psychoanalytically

oriented therapist, a sociologist, a logician-philosopher, a marriage and family counsellor and an existential social worker". In our current state of financial stringency, can we trust our much more pedestrian "multi-disciplinary team" to fit this bill?

This is a scholarly and important book about suicide. It may not break new ground but as a fresh and elegant synthesis of ideas on a much trodden upon subject, it is a pleasure to read. And although some will find parts of it somewhat esoteric (as many as 40 pages, for example, attempt to unravel the "Psycho-Logics of Moby Dick") it would make a valuable addition to every psychiatric library. Some librarians may ponder whether to place it in the Arts or the Science section but, given our present knowledge on suicide, it should fit equally well in both.

D. J. PALLIS, *Consultant Psychiatrist, Graylingwell Hospital, Chichester.*

Assessment and Taxonomy of Child and Adolescent Psychopathology. By THOMAS M. ACHENBACH. London: Sage Publications. 1985. Pp. 200. £19.75 (hb), £10.00 (pb).

The Sage series on *Developmental Clinical Psychology and Psychiatry* is a welcome source of information on children and adolescents.

In this third volume, Achenbach authoritatively discusses the central themes of assessment—"identification of the distinguishing features of each case"—and taxonomy—"the grouping of cases according to their distinguishing features"—in the psychopathology of the young.

Some books dealing with psychopathology have an ideological undercurrent reflecting the author's commitment to one set of beliefs. This unbiased monograph is a "meta-analysis" comparing the currently fashionable clinical and research assessment and taxonomic paradigms dealing with psychopathology.

Achenbach discusses the problems encountered in clinical information processing, and clarifies the ubiquitous nature of judgemental biases relating them to current assessment practices. Dealing in turn with the medical, psychodynamic, psychometric and behavioural paradigms and then focusing on the Kraepelinian, psychodynamic and multivariate taxonomic paradigms, he leaves the reader uncomfortably convinced that information processing biases exist to such a degree in each framework that the notion of "unbiased objectivity" is an illusion.

He systematically classifies the sources of distortions inherent in each system, highlighting the complexities confronting the clinician and researcher in dealing with the psychopathology of the child and adolescent.

Achenbach's exposé should not be dismissed (as he states) as a philosopher's hobby horse. Rather his critical analysis and synthesis should stimulate creative discourse, heighten the necessary tensions between firmly held, polarised views on the nature of psychopathology and eventually, one hopes, lead to a unified theory of development that includes a sound rationale for assessment, taxonomy and intervention in dealing with troubled youngsters.

The Retreat, York

for Psychiatric Illnesses

Founded in 1792 by the Quaker, William Tuke, who established the tradition of concern for patients as individuals The Retreat is a 200-bedded private registered nursing home surrounded by extensive grounds on the outskirts of the historic City of York. It is easily reached by rail and motorways.

Care and treatment is offered for all types of psychiatric illness on the short or long term in a sympathetic and friendly atmosphere. Patients suffering from neuroses, psychoses, alcoholism and dementia are treated by the full-time consultant psychiatrists in surroundings suitable for their individual needs. Outpatient facilities are available by appointment with the consultant medical staff.

The Nursing Home is a registered charity and is able to offer inclusive care in shared accommodation from £32.00 per day or in single rooms at slightly increased charge. The Nursing Home is recognised by the main private patient schemes.

For further details apply to The Medical Director, The Retreat, York YO1 5BN (Telephone 0904 412551).

THE BRITISH JOURNAL OF PSYCHIATRY

September 1986

Vol 149

Acc.
14.9.87

ISSN 0007-1250

Published by authority of
The Royal College of Psychiatrists

NOTICE TO CONTRIBUTORS

1. *The British Journal of Psychiatry* is published monthly under the auspices of the Royal College of Psychiatrists. The *Journal* publishes original work in all fields of psychiatry. Communications on general editorial matters, including manuscripts for publication, printed matter, and books for review, should be sent to *The Editor, The British Journal of Psychiatry, 17 Belgrave Square, London SW1X 8PG*.

2. Contributions are accepted for publication on the condition that their substance has not been published or submitted for publication elsewhere. The *Journal* does not hold itself responsible for statements made by contributors. Unless so stated, material in the *Journal* does not necessarily reflect the views of the Editor or the Royal College of Psychiatrists.

3. Published articles become the property of the *Journal* and can be published elsewhere, in full or in part, only with the Editor's written permission.

4. Manuscripts accepted for publication are subject to copy-editing, and to editorial changes required for conformity with *Journal* style.

5. We regret that papers unsuitable for publication will not be returned.

6. **General advice to authors** In the assessment of manuscripts submitted to the *Journal*, great importance is attached to clarity and brevity of expression. Authors should read *General Notes on the Preparation of Scientific Papers* (3rd ed. 1974, £0.45, from The Royal Society) and/or Judith Butcher's *Typescripts, Proofs and Indexes* (1980, Cambridge University Press, £2.95). Spelling should follow the *Concise Oxford Dictionary*.

The standard of statistical work in papers submitted for publication has proved to be very variable. Authors using any statistical methods at all are strongly advised to study the paper 'Statistical guidelines for contributors to medical journals' (D. G. Altman *et al*, *British Medical Journal*, 7 May 1983, **286**, 1489-1493) at the earliest possible stage in preparing their work for publication.

7. **Manuscripts** Two high-quality copies should be submitted and the author should retain a copy. Articles must be typed on one side of the paper only, **double spaced with wide margins**, and all the pages must be numbered sequentially, starting with the title page.

a. The **title** should be brief and to the point. If necessary, a sub-title may be used to amplify the main title. The names of the authors should appear on the title-page, and **their names, degrees, affiliations and full addresses at the end of the paper**.

b. A **summary** should be given at the *beginning* of the article. It should be brief and factual and not normally more than 150 words.

c. **References** should be listed **alphabetically** at the end of the paper, **the titles of journals being given in full**. Authors should follow *Journal* style for the reference list and study the examples given below. Titles of books and journals are printed in *italic* and should therefore be underlined on the typescript. Reference lists not in *Journal* style will be returned to the author for correction.

Authors should check that the text references and the reference list are in complete agreement as regards dates and spelling of names. The text reference should be in the form: 'Smith, 1971)' or 'Smith (1971) showed that ...'

DURKHEIM, E. (1897) *Le Suicide*. Paris. Translated (1952) as *Suicide: A Study in Sociology*, by J. A. Spaulding & C. Simpson. London: Routledge & Kegan Paul.

KENDELL, R. E. (1974) The stability of psychiatric diagnoses. *British Journal of Psychiatry*, **124**, 352-358.

RUTTER, M., TIZARD, J. & WHITMORE, K. (1970) *Education, Health and Behaviour*. London: Longman.

SCOTT, P. D. (1974) Definition, classification, prognosis and treatment. In *Pathology and Treatment of Sexual Deviation* (ed. I. Rosen) Oxford: Oxford University Press.

'Personal Communications' need written authorisation.

d. **Symbols and abbreviations** Follow *Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors* (3rd ed. 1977), £2.00, available from the Publications Office of the Royal Society of Medicine. Terms or abbreviations which might not be understood by the average reader should be explained at first occurrence.

e. **Tables and Figures** Each table should be on a separate sheet, with an adequate heading; table and heading should be self-explanatory without reference to the text. The desired position of the table relative to the text should be indicated in the left margin.

Figures should be individual glossy photographs, or other camera-ready prints, *not* photocopies, clearly numbered and captioned below. Avoid cluttering figures with explanatory text which is better incorporated succinctly in the caption. A figure intended to occupy a single column should be drawn (or photographed) 80-110 mm wide to allow for a 2/3 reduction; a figure requiring the whole width of the page should be 180-210 mm wide. Lettering (film-set or stencil) should be 12pt sans (initial capital for the first word only) to give 8pt on the printed page. Labels on graphs should read parallel to the axes. Units must be clearly indicated and should be in brackets (*note*—'litre' should be spelled out in full unless modified to ml, dl, etc.).

f. **Photographs** Prints must be taken directly from the original b/w negative (not, for example, from a colour slide or a printed page) and should be glossy and sharply focussed. Labels, arrows, etc. should be shown on a duplicate print or overlay. Do not write anything on photographic prints, and do not use staples or paper-clips on them. These procedures apart, all the comments on figures and tables apply equally to photographs.

8. **Proofs** A proof will be sent to the senior author of an article. Reprints, which are prepared at the same time as the *Journal*, should be ordered when the proof is returned to the Editor.

9. **Letters to the Editor** Letters should not exceed two double-spaced typed pages. They will be edited for clarity and conformity with *Journal* style and may be shortened. There should be no more than five references; tables and figures cannot be used.

When there seems to be no way out.

Ticehurst House was established as a psychiatric clinic more than 200 years ago. Today it retains its position at the forefront of psychiatric care.

The reputation of Ticehurst House stems from the comprehensive service it offers to patients and to the medical and psychiatric professions.

The psychiatric team at Ticehurst House offers a full spectrum of treatments in the care of short and long term patients and specialises in the active care of short term patients, the treatment of alcoholics and the assessment and treatment of psychogeriatric patients.

The hospital responds promptly to requests for out-patient consultation and admission of patients. There are excellent liaison procedures between Ticehurst House and outside Consultants and G.P.s.

The special facilities at Ticehurst House include a psychogeriatric assessment unit, the Newington Alcohol Treatment Unit and facilities for day care patients.

Within the grounds of the hospital Highlands Lodge offers high quality accommodation for low dependency patients under the care of Consultants and experienced nursing staff.

Ticehurst House enjoys an excellent reputation for its cuisine. Bedrooms are spacious and equipped with nurse-call systems.

It is easily accessible by both road and rail, being close to Wadhurst in Sussex (70 minutes from Charing Cross), and stands in forty-eight acres of delightful gardens and grounds.

For further information write or telephone The Medical Director, Ticehurst House, Ticehurst, Near Wadhurst, Sussex TN5 7HU. Telephone (0580) 200391.

EXAMINATION TECHNIQUES FOR THE MRC PSYCH

This one day course will be run at Charing Cross Hospital on Saturday 1st November starting at 9.30 a.m. Topics to be covered include:

- 1) Writing an essay with a mock paper
- 2) MCQ with a 30 question mock paper
- 3) Making the most of time with the patient
- 4) Presentation in the clinical and viva with video feedback from mock exam situation with senior psychiatrists as examiners.

Course Organiser, Dr Chris Thompson.

For further information contact: Tricia Carroll, Department of Psychiatry, Charing Cross & Westminster Medical School, 24 St Dunstons Road, London W6, Tel. 01 748 2040 ext. 3010.

The course is approved for study leave expenses under HM(67)27.

Final date for registration is Friday 17th October.

Vital New and Revolutionary Principles of
Human Psychology, Physiology And Psychogenic Pathology

by

M. S. Rao, 2nd revised edition, 832 pages, demy 8vo, hard bound, art jacket, £12.

"A book of encyclopaedic proportions it covers all aspects of the human psychology. It is replete with case-histories of mental (psychogenic) disorders, of all types, their analysis and treatment. . . The work stems from the actual experience of a successful clinical psychologist that the author is. He has not only explained, in details, mental (psychogenic) disorders, but has also shown how to correct them—and even to prevent them. . . He is abreast of the latest developments in the psychiatric field in other countries"—*The Hindustan Times, Sunday Magazine, Books Review Section.*

This book shows that while the psychology and physiology of the other animals are simply instinctive and self-preservative, the peculiar human psychology and physiology (because of the unique human brain) are complex; and, besides being instinctive, they are also idea-determined, intellectual and super-instinctive, so that they are naturally very alterable and *pervertible* or disorder-prone, so that they often become counter-instinctive, suicidal and self-destructive, as shown in cases of schizophrenia, hypochondria, hysteria, melancholia, paranoia, etc., called 'neuroses and functional psychoses', or 'the major psychiatric disorders', in today's psychiatry and abnormal psychology.

This new book now really explains the precise psychologic causation, and *real* (ideo-emotional) nature, of these disorders (pathology) of the human mind and body, or of human psychology and physiology—explains with vital new principles, and new terms and concepts, with 'new ideas' or new theories, and explains so clearly and effectively that they all can now be cured or corrected, and prevented, as said in the review above.

This book also shows clearly how this new human psychology has now become an integral part of the human health science (physiology and medicine), and its most important part, so that this science will now be called *human psychology, physiology and medicine* (therapeutics). These are obviously revolutionary developments in this most vital human science, which will now effectively ensure all-round human health or well-being. This is what Prof. Coleman means to say (below).

This book also shows how the very special (alterable and *pervertible*) human psychology is also corrigible, and improvable or *supervertible*, so that we are now able to improve one's mental health (rectitude), with hopes and ambitions, with new will-power, courage and self-confidence.

It is due to these vital developments, and on studying the so-many explained and cured cases in this 'excellent' book that—

Dr James C. Coleman, Professor of Psychology, University of California, author of the famous textbook *Abnormal Psychology and Modern Life*, 5th edition, says about this book.

'A review of your outstanding book was most rewarding.

I express my sincere appreciation of your excellent book. The (new) basic premises on which your book is based are quite sound. I compliment you on this concise representation, and on the scholarly and outstanding text. It is a most interesting, informative and scholarly work. . . a most distinguished book. . . It will be warmly received and widely read in India as well as other countries' Similarly—

Dr Vinoda N. Murthy, Professor of Clinical Psychology, National Institute of Mental Health and Neurosciences, Bangalore, writes about this book, 'The book gives a lot of information on the psychologic factors (that work) in mental health and mental illness. . . This Institute teaches postgraduate diploma courses to doctors, to train them as psychiatrists. . . Your book may be prescribed. . .'

Even the Orthodox Psychiatrists (generally committed to Kraepelinian and genetic theories) appreciate and recommend these 'new ideas' or new theories of this book. Thus, Prof N. S. Vahia, a senior psychiatrist of India, says in a long review of this book in—

The Indian Journal of Medical Sciences, "The author's view-points deserve serious consideration by all those physicians, psychiatrists and clinical psychologists interested in new ideas."

The Indian Journal of Psychiatry also similarly says about this new book, 'Pathogenesis of all serious psychiatric disorders has been explained, by ideogenic mechanisms (by ideo-emotional brooding, etc) which deserve exceptionally serious attention of all research workers (in psychology and psychiatry).' No other book on psychology or psychiatry has elicited such warm opinions.

So, obviously, this is a book for all psychologists, psychiatrists, general medical men, and other intellectuals, educationists etc., and for all libraries. It is already in the more-important libraries of London. Published by Universal Psychology Publishers, D-36, Subhas Marg, Jaipur-1, India. London distributors:

Books From India, Ltd.,

Lord Chancellor's Medical Visitors

The Lord Chancellor invites applications for an additional appointment to the panel of part-time Medical Visitors. Applicants must be Fellows or Members of the Royal College of Psychiatrists.

Medical Visitors work to the Court of Protection which supervises the property and affairs of persons who by reasons of mental disorder are incapable of managing for themselves. They visit Patients when it is considered that a specialist opinion on their capacity would be helpful.

Remuneration will be on the basis of a fee normally not less than £63 (at present under review) paid for each visit undertaken. Travelling costs are reimbursed and a subsistence allowance is payable in respect of absences from home on duty.

The Visitor to be appointed will be expected to carry out about 6 visits a year, in Wales, Hereford and Worcester and Shropshire. Reserve Visitors for other areas may also be needed.

Applications should be sent to Mr I. R. Tapster, Lord Chancellor's Department, Neville House, Page Street, London SW1P 4LS by not later than the 30th September 1986.

Application forms will be provided on request to that address, or by telephone to 01 211 8084.

UNIVERSITY OF LONDON NORTH THAMES PSYCHIATRY MEMBERSHIP COURSE

The Autumn term of the course will be held in the Post-graduate Medical Centre, at Channing Cross Hospital. The Royal College of Psychiatrists have recently agreed to major alterations to both parts of the MRC Psych Exam and in accordance with this, the old course will be abandoned and replaced with a fresh approach to teaching of psychiatry and the basic sciences for the new exam. When fully operational six modules will be offered. During this transitional term, Module 1 is offered which is appropriate to Part I. For Part II the course continues as usual this term for the last term before modifying its syllabus in accordance with the new exam.

Module 1. To be held Tuesday afternoons from 3.00–6.15 p.m. from 7th October to 9th December to include Basic Clinical Skills; Descriptive Psychopathology; Neurosis; Affective Disorder; Schizophrenia; Acute and Chronic Organic Brain Syndromes; Dynamic Psychopathology—personality and personality disorder; Basic Psychopharmacology.

Part II, Term II. To be held Thursday afternoons from 3.00–6.15 p.m. from 9th October to 11th December to include Neurotic illness; Personality disorders; Affective Illness and Behaviour Therapy

Approval has been given for study leave and expenses under HM(67)27. Enquiries to Tricia Carroll, Course Administrator, Department of Psychiatry, 24 St Dunstons Road, London W6. Tel (01) 748 2040 x 3010.

West Midlands Institute of Psychotherapy

INTRODUCTORY COURSE IN DYNAMIC PSYCHOTHERAPY

An introductory course in DYNAMIC PSYCHOTHERAPY will be held at Uffculme Clinic, Birmingham, beginning on 20th January 1987. The course will be held on Tuesday afternoons and will extend over a period of two years.

Throughout the two year course members will attend a small group. The first year will also include seminars on both relevant theory and practice, together with case discussions.

Those who complete the course satisfactorily will be offered Associate Membership of the West Midlands Institute of Psychotherapy.

The programme is open to members of the medical and nursing professions, social workers, probation officers and other related disciplines.

The closing date for applications is *30th September 1986*. Shortlisted applicants will be required to attend for interview on Wednesday, 22nd October 1986, at 2 p.m.

Fees for the 1987/8 course will be £260 per annum.

For further information and application forms, please contact: Mrs. Valerie Peake, Secretary W.M.I.P., Uffculme Clinic, Queensbridge Road, Birmingham B13 8QD.

Tel: 021-449-4481, ext. 237. Monday/Tuesday/Thursday.

PSYCHIATRISTS

OFFICE OF PSYCHIATRIC SERVICES

VICTORIA

The Garden State

The Office of Psychiatric Services, Health Department Victoria, was created on the 7 February, 1986, as an innovative approach to the provision of psychiatric services to the community, reflecting the high profile and priority afforded to mental health services by the State Government.

We are now seeking to attract creative and energetic specialist psychiatrists to provide clinical expertise and leadership in our rapidly expanding programme delivery areas.

We offer you EMPLOYMENT

SYMPOSIUM ON BEHAVIOURAL PSYCHOTHERAPY

This one-day Symposium will cover the theory and background of behavioural psychotherapy and specific topics of clinical interest, including the treatment of phobias and anxiety, sexual and marital problems and obsessional illness. The roles of the psychologist and nurse practitioner will also be discussed.

Part of the programme will include small workshops with the individual speakers as well as discussion time.

Speakers will include:— Professor I. Marks, Professor J. Gray, Dr J. Bancroft, Dr J. Cobb and Mr S. Shrubbs.

This one-day Symposium will be held on:

Friday 28 November 1986

at

**The Royal Society
6 Carlton House Terrace
London, SW1Y 5AG**

The cost of registration will be £20 (£10 for junior medical staff.)

For further details of speakers and their specific topics and for registration forms, please contact: **Diane Carter, Charter Clinic, 1/5 Radnor Walk, London, SW3 4PB. Tel no 01-351 1272.**

Infant Depression

Paradigms and Paradoxes

1986 27 tables Approx 375 pages
ISBN 3-540-96343-X In preparation

Infant Depression: Paradigms and Paradoxes provides a unique study of the etiology of depression and depressive-like phenomena in infants. The book isolates key developmental milestones important for analyzing incipient depressive-like symptoms

G. A. Gladstein and Associates,
University of Rochester

Empathy and Counseling

Explorations in Theory and Research

1986 17 figures, 39 tables Approx 210 pages
ISBN 3-540-96358-8 In preparation

Dr. Gladstein and his associates, through theory and new empirical research, explore the various types of empathy from their development to the roles they play in counseling and similar helping processes. At the center of Gladstein's idea is a four-stage process involving perception, affective reverberation, cognitive analysis, and communication

Theories of Group Behavior

Editors: B. Mullen, Syracuse,
G. R. Goethals, Williamstown

1986 Approx 13 figures, 4 tables
Approx 235 pages
(Springer Series in Social Psychology)
ISBN 3-540-96351-0 In preparation

Theories of Group Behavior provides thorough and concise presentations of the major theoretical perspectives on group behavior. Theoretical approaches which have dominated research on intrapsychic processes, such as self-awareness, cognitive dissonance, and social cognition, are applied in order to help understand group phenomena

Treatment of Schizophrenia

Family Assessment and Intervention

Editors: M. J. Goldstein, Los Angeles,

Mental Illness Among Immigrant Minorities in the United Kingdom

M. LONDON

Cross-cultural studies on immigrants from Pakistan and the New Commonwealth are reviewed, with emphasis on epidemiology and differences in clinical presentation. Their referral to the psychiatric service is also examined and deficiencies are noted. Awareness of transcultural issues among health professionals need to be increased in order to achieve diagnosis and improvements in health care.

Just under 3% of the population in Britain today were born in the countries of the New Commonwealth and Pakistan (Registrar-General, 1983). The majority came from the West Indies and the Indo-Pakistan subcontinent during the 1950s and 1960s to satisfy the need for unskilled labour. Others, mostly from Africa, arrived for the purpose of further education. With the passage of time a British-born generation has emerged, but they have received relatively less attention from researchers than their parents who migrated to this country. This is largely due to the practice of using the place of birth to identify subjects for research.

Earlier migrations from Ireland and Eastern Europe have been associated with increased rates of psychiatric disorder (Clare, 1974; Murphy, 1955; Mezey, 1960). Murphy (1977) has put forward three explanations for this relationship. Firstly, the observed differences may have little to do with the migration itself, and may only reflect a different pattern of disorder in the migrant's culture of origin. The second explanation, known as the selection-theory, applies mainly to schizophrenia and suggests that during the early incipient phase of the illness the likelihood of migration is increased because of failing interpersonal relationships (Ødegard, 1932). The third explanation lies in the stress associated with migration and resettlement. Many endure hardships, such as split families, prejudice, poor housing and employment (Cox, 1977; Hashmi, 1968; Littlewood & Lipsedge, 1982), and single men may experience sexual difficulties (Risso & Boker, 1968). Social isolation and insecurity provide fertile ground for paranoia (Eitinger, 1960). To cope successfully one has to undergo a series of internal changes very similar to the process of bereavement, in which the old culture is abandoned and the threat to one's identity resolved (Garza-Guerrero, 1974).

Recent reviews of the transcultural research undertaken in this country have noted the problems

in gauging the true state of psychiatric morbidity among immigrants (Littlewood & Lipsedge, 1979; Rack, 1982a; Cochrane, 1983). Earlier studies (Gordon, 1965; Hems, 1967) failed to recognise demographic differences when comparing results with the native British population. Immigrants have a younger age structure and show an excess of males in the initial stages of immigration, before being joined by their wives and children. British-born control groups are often drawn from the same inner city areas where most immigrants reside. These areas are known to have unusually high levels of morbidity (Faris & Dunham, 1939; Hare, 1956). It is also uncertain whether variables such as social class and occupation carry the same meaning for each group, as menial employment in this country may nevertheless represent an improvement over a peasant economy (Stopes Roe & Cochrane, 1980). Accurate assessment is often hampered by lack of epidemiological data for the country of origin. Much research also assumes a homogeneity among immigrant groups, which is only partly justified. Although many West Indians come from Jamaica, others originate from islands that differ markedly in their culture, size and economic activity.

Immigrants from the Indo-Pakistan subcontinent have been grouped into those from India and Pakistan, neglecting religious, cultural and language differences. Some studies have inappropriately placed Asians from East Africa together with those from the subcontinent, thereby failing to take into account the many differences – in particular, their arrival in this country as refugees. Finally, there are difficulties of small sample size, especially in the evaluation of individual diagnoses.

West Indians

Studies based on hospital admissions (Cochrane, 1977; Dean *et al*, 1981; Carpenter & Brockington,

1980) and on the Camberwell Case Register (Bagley, 1971a; Rwegellera, 1977) show an increased overall rate of disorder among West Indians. The sex difference is as expected, with an excess of females (Cochrane, 1977; Dean *et al*, 1981, Carpenter & Brockington, 1980). A recent study (Ineichen *et al*, 1984) asserted that there was no significant difference in the rate of voluntary hospital admissions between West Indian and English patients living in the centre of Bristol. One in six of the population in these inner city districts belonged to ethnic minorities, and this was reflected in the proportion of voluntary admissions during 1981: 30 out of 175 admissions. However, although 16 admissions were of West Indians the authors made no direct comparison with census statistics for West Indians alone. Furthermore, as already noted, comparisons with inner city areas may in itself indicate an excessively high rate. By contrast, West Indians were noticeably over-represented among compulsory admissions (Harrison *et al*, 1984), numbering 27 out of the 89 formal admissions between 1978 and 1981.

Since they sample hospital in-patients, these studies are biased in favour of the major psychiatric disorders and may therefore relate more narrowly to those illnesses that require admission rather than to the total psychiatric morbidity. A more representative sample may be provided by the Case Register, which documents all contacts with the psychiatric service in a defined area. However, not all psychopathology reaches the attention of the psychiatrist. Two small general practice studies (Pinsent, 1963; Kiev, 1965), undertaken on what were at the time recently arrived immigrants, showed an increased morbidity; no similar studies appear to have been carried out since then.

With a few exceptions (Rwegellera, 1977; Hems, 1967) schizophrenia appears to be the commonest diagnosis (Cochrane, 1977; Dean *et al*, 1981; Gordon, 1965; Bagley, 1971a; Bebbington *et al*, 1981). This is in keeping with international research findings (Sanua, 1969) and lends support to the selection theory. However, those British studies that have defined their categories more strictly have shown an increase of atypical psychosis. Tewfik & Okasha (1965) found that only 155 of psychotic West Indian in-patients suffered from an illness typical of those seen in Britain: half suffered from mania and half from chronic hebephrenic schizophrenia. The remainder appeared to have a schizophrenia-like illness characterised by a continuum of symptoms with confusion and paranoid symptomatology at either end. The overall prognosis was good, with 43% making a complete recovery and 77% returning to work. The authors felt that this illness was a dissociative

one and a response to stress. Similarly Gordon (1965) found schizoaffective disorder among a quarter of his admissions, and also diagnosed acute schizophreniform reaction with a greater than average frequency. Less than 5% of his series had a positive family history for psychosis, and only 7% had been hospitalised prior to migration.

These early studies may be criticised on methodological grounds, and comparisons with British-born patients are unreliable. Nevertheless, these clinicians did find that a large proportion of the West Indian patients that they treated presented atypically. Despite the passage of years these atypical psychoses have been reflected in more recent epidemiological research. On reanalysis of hospital diagnoses Carpenter & Brockington (1980) showed that nuclear schizophrenia fell from a previously high rate to within the expected British range, while paranoid psychosis was increased. A criticism of this study, however, is that the ethnic minorities were insufficiently differentiated. Africans and West Indians were combined for the purpose of hospital diagnosis, and the reanalysis was carried out on immigrants as a whole. Littlewood & Lipsedge (1981b) studied a small group of sixteen patients with religious delusions but lacking first rank symptoms. They were typically women belonging to charismatic churches whose psychoses followed a precipitating event and whose illness was of short duration. With the passage of time, and presumably the influence of a dominant culture, the presenting picture changed to one of depression. Although the acute psychotic reaction is widely recognised in developing countries (German, 1972; Littlewood & Lipsedge, 1981b), it is not a diagnostic category generally used by British psychiatrists. The blanket use of schizophrenia as a diagnosis may mask such distinctions.

Symptoms prominent in schizophrenia and allied disorders are religious beliefs (Kiev, 1963; Gordon, 1965; Ndeti & Vadher, 1985b) and paranoid delusions (Gordon, 1965; Rwegellera, 1977; Ndeti & Vadher, 1984c). The former arise out of the fundamentalist Christian beliefs of the West Indian community (Kiev, 1963), while the latter has a recognised association with migration. Schneider's first rank symptoms are present in 43–53% of patients with schizophrenia (Chandrasena, 1980; Ndeti & Vadher, 1984d) as opposed to 72% of British-born patients (Mellor, 1970). Disturbed behaviour also appears to be more common prior to admission (Harrison *et al*, 1984; Rwegellera, 1970).

The sex ratio for patients with affective disorders may be more exaggerated than that for British patients (Cochrane, 1977; Bebbington *et al*, 1981; Hems, 1967) but overall frequencies are similar

(Dean *et al.*, 1981; Carpenter & Brockington, 1980; Bagley, 1971a). A community survey noted that the sex ratio narrowed with age, although the severity of the depression was not clearly defined (Burke, 1984). Mania is significantly more common among West Indians (Leff *et al.*, 1976; Bebbington *et al.*, 1981). Rack (1982b) has attributed this to reactive mania, a type of stress reaction (Tyrer, 1982). Alternatively, cyclothymic individuals may be more inclined to migrate.

The results for neuroses and personality disorders are inconsistent, with some studies showing reduced rates (Cochrane, 1977; Bebbington *et al.*, 1981; Bagley, 1971a; Gordon, 1965), increased rates (Rwegellera, 1977) or no apparent difference (Dean *et al.*, 1981; Carpenter & Brockington, 1980) when compared with British control groups. This ambiguity is significant because these 'lesser' disorders are much commoner than the major psychoses among British-born patients. This discrepancy may reflect a difference in the utilization of the psychiatric services.

Burke (1976a, 1979) found the attempted suicide rate among those who had migrated to be greater than the indigenous rate for Jamaica, but it had not reached the same level as the native British population. He attributed this to the problems of acculturation and adaptation to an industrialised urban environment. However, this study was a retrospective one, and the inclusion of only those cases where the place of birth had been recorded may have biased the sample. The suicide rate is less than that of the native British rate, and is also one of the lowest among all the ethnic minorities (Cochrane, 1977; Adelstein & Mardon, 1975). As shown by research in Australia, the indigenous pattern of suicide among immigrants may be expected to persist unchanged for many years (Burvill *et al.*, 1982).

West & Farrington (1973) found an increase in delinquency among West Indian boys despite a low rate of criminality in their parents (Rutter *et al.*, 1975). Although Burke (1982) ascribed this to repeated separation experiences, his study of eighteen female offenders was too small to substantiate his assertion, particularly with regard to male offenders. Studies of West Indian children showed an abnormally high rate of conduct disorders (Rutter *et al.*, 1974; Nicol, 1971) of a kind that was unusual in many respects. It occurred predominantly in girls, was specific to the school situation and was not associated with impaired peer relationships (Rutter *et al.*, 1974). It also correlated with poor performance on tests of intellect and reading abilities (Yule *et al.*, 1975). Suggested explanations included overcrowded home conditions, deprivations in early life,

particularly for those born in the Caribbean islands, and the poor quality of the schools themselves (Rutter *et al.*, 1974; Yule *et al.*, 1975). Cochrane (1979) replicated Rutter's study six years later, and although he found some support for the previous trend it failed to reach statistical significance. He concluded that the educational system may have successfully assimilated immigrant children during those intervening years.

In order to evaluate epidemiological findings accurately one must consider the interaction and referral patterns of West Indians with the Health Service. Burke (1984) concluded that general practitioners failed to reach a psychiatric diagnosis for 21.3% of West Indians identified as being depressed in a survey. This was significantly greater than the 12.8% identified in an English control group. These subjects, drawn from a general practice register, were initially screened with the General Health Questionnaire and probable cases were then interviewed. Although depression was operationally defined the criteria were not clearly described; nor was it possible for the assessment to be blind.

Subsequent referral of West Indians to the psychiatric service differs from the indigenous British population both in the high rate of compulsory admissions and in the degree of involvement by an agency other than a general practitioner. Compulsory admissions have correlated with the excessively high rate of psychosis among West Indian admissions (Harrison *et al.*, 1984; Rwegellera, 1980; Littlewood & Lipsedge, 1981a; Gordon, 1965). Rwegellera (1980) analysed the Camberwell Case Register for psychiatric referrals during the 1960s, including out-patients and domiciliary contacts. Significantly, only half of the West Indian patients were referred by general practitioners or hospital doctors, in contrast to 61% for a well-matched English control group. Many were brought by relatives. Another study of hospital admissions during the 1960s found support for this trend, although West Indians were not differentiated from other New Commonwealth immigrants (Hitch & Clegg, 1980). Recently, Harrison *et al.* (1984) showed greater police involvement in the referral of West Indians from an inner city area, compared with indigenous British patients living in the same locality. Littlewood & Cross (1980) also found self-referrals to be more common among a mixed group of New Commonwealth immigrants. There are correlations between compulsory admissions, psychosis and disturbed behaviour (Harrison *et al.*, 1984; Rwegellera, 1980). Relatives may prefer to resort to legal sanctions and call the police to avoid the stigma of mental illness (Hitch & Clegg, 1980). As a minority group West Indians may also feel alienated from

society's institutions, and this may affect their attitude to general practitioners. Their reluctance may also be related to ignorance of how a GP can help, or the belief that he is not the correct person to consult regarding mental illness (Rwegellera, 1980). The authorities may be less tolerant of deviancy among immigrant groups, and some have regarded compulsory admission as a form of social control (Mercer, 1984). Most importantly, if the illness remains untreated for a long period the patient may become more seriously ill, losing insight and necessitating a formal admission. Harrison *et al* (1984) found that many West Indians formally admitted were young women living with their families. Despite this close contact, many were detained by police in public places and brought to see a psychiatrist. In view of the research pertaining to atypical psychosis one may suspect that earlier intervention and treatment may prevent the psychosis developing. Although Littlewood & Lipsedge (1982) note that the sudden onset of the acute psychotic reaction may prevent early detection, the psychological well-being of these patients prior to onset has not been proven. Depression and minor psychiatric illness may remain untreated for the reasons discussed above. Deterioration may lead to a psychosis through subcultural or dissociative mechanisms. This is an area which requires further research.

At its height, immigration from the West Indies was unrestricted and even encouraged by British employers through recruiting drives. Although such conditions favour the selection model, this may only partly explain the apparent excess of psychoses. The duration of stay in the United Kingdom prior to the onset of symptoms is a relatively lengthy one of 5–10 years (Littlewood & Lipsedge, 1981a; Bagley, 1971a). This suggests that stress plays a significant role, whether as a precipitating factor in those biologically predisposed (Bagley, 1971a) or as an aetiological agent in a reactive psychosis (Littlewood & Lipsedge, 1981b). Such stress has many facets. Bagley (1971b) advocated a model of 'status inconsistency' where the subject strives to achieve goals but fails to recognise the restriction of opportunity implicit in the environment. The discrepancy between the perceived ideal and the true self results in loss of self-esteem. Drawing on the learned helplessness model, Fernando (1984) argued that racism engendered depression by denying its victim any control over external events. Poor self-esteem, rejection and loss exacerbate the phenomenon. These complex theories are difficult to test in practice, as it would require a large, well-constructed study to eliminate the many associated factors. In a community study measuring individual stresses Burke (1980) was

unable to demonstrate overall differences, although he noted an emphasis on interpersonal conflicts among West Indians which may have been enhanced by greater isolation from neighbours and relatives.

Indians and Pakistanis

Epidemiological studies on overall morbidity have produced conflicting results. Carpenter & Brockington (1980) showed that Asians have an increased rate of first-time hospital admissions, although they failed to differentiate between those born in India and Pakistan. Dean *et al* (1981), with closer attention to the place of origin, showed that Pakistanis have fewer first-time admissions than the British, while Indians have a higher rate. Cochrane (1977) analysed national hospital admissions for 1971 and showed that both Indians and Pakistanis have fewer hospital admissions than the British (including readmissions). The comparability between the studies by Dean *et al* (1981) and Cochrane (1977) is hindered by differences in techniques used to analyse the data. Furthermore, Dean *et al* (1981) were able to identify the place of birth in a higher proportion of their sample; this information was absent in 30% of national admissions. A further source of error is the hidden number of patients who, though born in India, come from British colonial families.

Schizophrenia is the commonest hospital diagnosis in both populations, and occurs with a higher than expected frequency (Cochrane, 1977; Dean *et al*, 1981; Carpenter & Brockington, 1980; Shaikh, 1985). When readmissions are excluded, Pakistani men fall to within the British range (Dean *et al*, 1981). Rack (1982b) has drawn attention to the pitfalls of diagnosing schizophrenia when English is not the first language and where cultural beliefs differ. Ndeti & Vadhver (1984d) found that Schneider's first rank symptoms were present in only 58% of Indian immigrants where schizophrenia was diagnosed according to the CATEGO programme. Unlike research on West Indians, atypical psychoses among Asians have received relatively little attention. When noted, they do not appear to be increased, although these studies were based on routine hospital diagnoses (Dean *et al*, 1981; Carpenter & Brockington, 1980).

Studies both of first admissions (Dean *et al*, 1981; Carpenter & Brockington, 1980) and the Camberwell Case Register (Bagley, 1971a; Pinto, 1970) show no significant difference in the rate for affective disorder in comparison with the native British population, although Cochrane (1977) found it to be comparatively less when all admissions for 1971 in England and Wales were analysed. In Asiatic and other

developing countries depression is characterised by prominent somatic symptoms, whereas those psychological features more usually recognised in the West may be concealed or even absent (Teja *et al*, 1971; Murphy *et al*, 1967).

In-patient studies show wide variations in rates for neuroses and personality disorders which nevertheless remain consistently less frequent than the psychoses (Cochrane, 1977; Dean *et al*, 1981; Carpenter & Brockington, 1980; Shaikh, 1985; Pinto, 1970). Clinical features of neuroses differ from those of British-born patients. Ndeti & Vadher (1984b) analysed the case notes of a mixed group of immigrants using the syndrome check list and CATEGO programme. In studying anxiety and related syndromes they found that the tension category, which comprises mainly physical symptoms, was significantly increased in African, Asian and Caribbean patients. In addition to this theme of somatisation, Rack (1982b) has also drawn attention to the effect of dissociation in hysteria. A pseudo-psychosis characterised by hallucinations is not uncommon in young Asian women and can be regarded as a means of communicating distress akin to the overdose in English patients.

Attempted suicide has increased following migration but remains less than the British rate (Burke 1976b). The principal method used is similar to that of English patients, having changed from corrosives and insecticides to psychotropic drugs. Surveys of childhood disorders using Rutter's method have shown a reduced rate of conduct disorder in Indian and Pakistani school-children (Kallarackal & Herbert, 1976; Cochrane, 1979). Cochrane attributed this to better psychological health among Asian immigrants, while Kallarackal & Herbert felt that the quality of Indian family life helped reduce any disturbance. There was an indication of increasing maladjustment with longer residence in the United Kingdom, but this failed to reach statistical significance.

Findings based on hospital admissions may be influenced by differences in utilisation of the psychiatric services. Some patients may avoid the service entirely and seek help from traditional healers. Aslam (Rack, 1982b) found that Hakims, practitioners using an Islamic system of medicine, diagnosed mental problems in a quarter of their patients. Many of these Asian immigrants complained of psychosexual difficulties. Brewin (1980) showed that Asians visited their general practitioner as frequently as British-born controls, yet their admission rate for psychiatric disorder was reduced. He concluded that general practitioners had not detected these disorders because of a failure of communication. The

unproven assumption behind this reasoning is that the distribution of psychiatric and physical illnesses were the same in each group. Although studies of mixed groups of immigrants show high rates of formal admissions (Hitch & Clegg, 1980), Shaikh (1985) reported no significant differences among Asians living in Leicester, even though schizophrenia was more commonly diagnosed. Pinto (1970) used the Camberwell Case Register to compare 49 Asian admissions, born in the Indian subcontinent, with an English control group matched for diagnosis. There was no significant differences in compulsory admissions, nor in the number of referrals by general practitioners. There was a higher rate of self-referrals by Asian patients and Asians did show a slightly longer duration of symptoms prior to admission. Pinto inferred from this that Asians may avoid seeking medical help, whether through ignorance or difficulties in communication. However, these conclusions are based on a small number of patients.

Cochrane undertook a series of community surveys using the Langner 22 Item Index to detect minor neurotic symptoms. He compared two samples of Indians and Pakistanis, selected to represent their respective communities by age and sex, with a matched British-born control group (Cochrane & Stopes Roe, 1977). Pakistani men scored significantly fewer psychological symptoms than the British controls, while all other scores were equivalent. The symptoms derived by the Langner index did not constitute psychiatric cases, and they were also elicited by lay research workers. A larger multi-centre study compared Indian and Pakistani-born with Irish-born subjects (Stopes Roe & Cochrane, 1980). Unlike the previous study this survey was randomised by the research worker choosing houses at random to visit. However, the sample was still limited to high density immigrant areas. The Pakistanis now achieved very high scores, while the Indians scored less than the Irish. The low score for Indians was supported by a similar study comparing Indian, Pakistani and British-born subjects (Cochrane & Stopes Roe, 1981).

On the basis of both his in-patient and community studies Cochrane inferred that Indians have less psychological ill-health than Pakistanis and that the two communities together suffer less psychiatric morbidity than the general British population. It is arguable whether the two types of studies can be used in support of one another, as they measure different phenomena. He speculated that the complex and restrictive nature of migration from the Indian subcontinent deterred all but the most determined and psychologically robust, resulting in a reduced morbidity among Asian immigrants. This lowered

morbidity has not been consistently demonstrated, and the discrepancies found between first time and total admissions may imply a low readmission rate. Asian patients may either receive greater support from their relatives than their British counterparts or they may return to the Indian subcontinent to seek treatment. Cochrane (1983) further speculated that improved socioeconomic status and upward mobility contributed to the low Langner scores among Indians (Stopes Roe & Cochrane, 1980). Pakistanis have lower socioeconomic origins and have experienced little upward mobility since arrival in this country. Nevertheless, he failed to demonstrate a correlation between social class and Langner scores among Pakistanis (Cochrane & Stopes Roe, 1981). A further consideration has been the degree of acculturation and exposure to the indigenous British culture. An insular lifestyle may protect against such stress and any resultant psychological problems (Westermeyer *et al.*, 1983). However, Pakistani women showed high Langner scores despite only 10% being at work (Stopes Roe & Cochrane, 1980).

The apparent contradictions between the studies discussed above may be lessened by a closer attention to the hidden variables. Where possible, samples should be large enough to take into account factors such as regional origin and religion. Research may also be valuably directed towards the areas of initial contact between the Health Service and the Asian patient.

Africans

Bagley (1971a), using a case register, analysed all contacts with the psychiatric services in Camberwell between 1966 and 1968. Of all the immigrant minorities the Africans showed the highest prevalence rate for all disorders, it being six times that of the indigenous British population. Using a different method Dean *et al.* (1981) confirmed this greater frequency among hospital admissions, although their sample included East African Asians.

The incidence of schizophrenia is high among African immigrants (Dean *et al.*, 1981; Bagley, 1971a; Rwegellera, 1977; Littlewood & Lipsedge, 1981a), and Copeland (1968) found that two thirds of West African in-patients suffered from schizophrenia or schizoaffective disorders, although research bias may have influenced the admission procedure (Rwegellera, 1980).

At the time these studies were carried out there was comparative freedom of movement for foreign students to enter the United Kingdom to study. Young Africans with a liability to schizophrenia and poorly adjusted within their own community may

have found it relatively easy to enter the United Kingdom as students with Commonwealth citizenship. Both Rwegellera (1977) and Littlewood & Lipsedge (1981a) found that the onset of symptoms occurred much earlier in Africans than in other immigrant groups. Characteristic features of the psychotic breakdown were paranoid delusions, magico-religious ideas and hypochondriasis (Ndeti & Vadher, 1984c, 1985b; Rwegellera, 1970; Littlewood & Lipsedge, 1981a). Paranoid ideas involving witchcraft or poisoning and directed towards fellow Africans were often found to be sub-cultural and to carry less weight when diagnosing schizophrenia. More typical of schizophrenia were delusions concerning Europeans and incorporating twentieth century technology (Copeland, 1968; Lambo, 1955; Littlewood & Lipsedge, 1981a). Grandiose delusions occur commonly in all types of psychoses among Africans and Jamaicans, and correlate with religious fervour (Ndeti & Vadher, 1985a; Lambo, 1955; Copeland, 1968). Disturbed behaviour is frequent and has been attributed to either learnt cultural role models or to gross anxiety engendered by magical beliefs (Rwegellera, 1980, 1970). Excluding first rank symptoms, Ndeti & Vadher (1984e) found that hallucinations of all types occurred more frequently in African, Asian and Caribbean patients compared with English-born controls.

In recent years Ndeti & Vadher have published a series of studies on individual symptoms based on a retrospective analysis of case notes using the Syndrome Check List. The retrospective nature of their work limits its value, but there are few comparable studies in the field. They found that first rank symptoms are present in only a third of schizophrenias diagnosed according to the CATGO programme (Ndeti & Vadher, 1984e). This agrees closely with Chandrasena (1980), who used the same instrument on a different sample. This goes some way towards confirming the reliability of these studies. In Nigeria 63% of patients with schizophrenia were found to have first rank symptoms (Carpenter & Strauss, 1974). An unusual feature in the United Kingdom is the distortion of the sex ratio such that men exceed women among those admitted for schizophrenia (Dean *et al.*, 1981; Rwegellera, 1977) although women do appear to have an increased admission rate for atypical psychoses (Dean *et al.*, 1981). Although the acute psychotic reaction is recognised in Africa (German, 1972), British studies dealing with this subject have been limited by sample size (Littlewood & Lipsedge, 1981b).

Affective and neurotic disorders in Africans share many of the features discernable in other New

Commonwealth groups. Ndeti & Vadher (1984a) noted that depression was rarely diagnosed by hospital clinicians, but when they reanalysed using the Syndrome Check List they found an excess of psychotic and retarded depressions. However, other studies suggest that affective disorders are well recognised and not under-represented (Dean *et al*, 1981; Rwegellera, 1977; Bagley, 1971a). Studies of first admissions and case register contacts (Dean *et al*, 1981; Bagley, 1971a) have shown a reduced rate for neuroses and personality disorders compared with the British-born. By contrast Rwegellera (1977), examining roughly the same data as Bagley, found that these disorders were increased to the extent of being the commonest diagnoses.

In a large, well-matched sample Rwegellera (1980) found that West Africans exceeded both West Indians and English controls in the rate of compulsory admissions and disturbed behaviour. Elsewhere he demonstrated a correlation between this disturbed behaviour preceding admission and social isolation (Rwegellera, 1970). Many were living on their own or with strangers, but there is no information available on the duration of their symptoms.

Epidemiological research carried out in Africa has shown the pattern of psychiatric morbidity to be similar to that of Western countries (Giel & van Luijk, 1969; Olatawura, 1982; German, 1972). Binitie (1981) found that less than 16% of new cases attending a clinic in Benin suffered from schizophrenia while up to 50% were treated for a psychoneurotic disorder. This is consistent with Rwegellera's findings, yet the bulk of British research has shown a marked excess of major psychoses.

As students Africans are exposed to stresses such as academic inadequacy, loneliness, career choice restrictions and accommodation difficulties (Anumonye, 1967). Nevertheless, of all immigrant groups African patients seem to conform most to the selection model. Now that the British government has ceased to fund universities for the training of overseas students, the nature of the African community in this country may be expected to change. This may in turn influence the future pattern of psychiatric morbidity.

Conclusion

Although 25 years have passed since the arrival of the first immigrants from the New Commonwealth, migration should not be regarded as a discrete event.

Adaptation to a new environment may be undermined in later life by crises of career, family or impending old age. Afro-Caribbeans have an increased rate of first admissions in the 35-45 year age group, a range which is atypical for both schizophrenia and affective psychosis (Carpenter & Brockington, 1980). Persistence of morbidity has also been demonstrated in earlier migrations (Hitch & Rack, 1980). It is not certain to what extent acculturation may cause pathology such as hysteria, somatization and the acute psychotic reaction to be relinquished in favour of symptoms more characteristic of the host population. That this morbidity is not static has been underscored by evidence of a shift away from psychosis towards depression in individual patients (Littlewood & Lipsedge, 1981b). Longitudinal studies would help clarify this, but research is hampered by problems of phenomenology. The theoretical perspective of psychiatry in this country will not readily accept concepts such as the reactive psychosis (Strommgren, 1974) and this should be borne in mind when interpreting epidemiological results. On the other hand, overcaution in assessing symptoms in culturally distinct patients may lead to an emphasis on the unusual or atypical disorder when a diagnosis such as schizophrenia may be more appropriate. A prospective study that did not rely on case records would help to improve our understanding.

The evidence suggests that earlier recognition and treatment of psychiatric disorder is needed. Education of health professionals may go some way towards facilitating access and improving the psychiatric care available. Accurate assessment of the immigrant patient demands adequate communication and an understanding of cultural influences (Cox, 1976, 1982). The emphasis on somatic complaints may delay diagnosis or direct patients to inappropriate hospital departments. Two areas where research may be of value are general practice and liaison psychiatry. The immigrant minorities are a factor which cuts across all psychiatric research, ranging from social psychiatry to clinical drug trials. An altered response to psychotropic drugs may arise out of diet, genetic differences in metabolism and cultural factors (Lewis *et al*, 1980; Allen *et al*, 1977). A wider acknowledgement of these issues would increase awareness and lead ultimately to improvements in health care. It also affords an opportunity to re-examine psychiatric concepts that have evolved within our own cultural frame of reference.

Depression in Mentally Handicapped Patients: Diagnostic and Neuroendocrine Evaluation

L. SIRELING

The dexamethasone suppression test was administered to 12 mentally handicapped depressed patients. One of the four patients with major depressive disorder, but none of those with other diagnoses, failed to suppress cortisol production. The International Classification of Diseases and the Newcastle Diagnostic Index were found to be unreliable for use with severely mentally handicapped patients. Modifications are proposed which would allow the Research Diagnostic Criteria and Hamilton Rating Scale for Depression to be applied to patients with any degree of mental handicap.

The simultaneous presence of mental handicap and depression is a great challenge to diagnostic skills, particularly when communication is exclusively non-verbal (Reid, 1972; Wright, 1982). A specific laboratory marker for depression would therefore be particularly welcome to psychiatrists working in the field of mental handicap. Evidence has steadily been accumulating of a disturbance of the hypothalamic-pituitary-adrenal axis in depressive illness (Schlessler *et al*, 1980): many depressed patients do not suppress cortisol production following the administration of a synthetic glucocorticoid, and the dexamethasone suppression test (DST) has been proposed for the diagnosis of endogenous depression (Carroll *et al*, 1981). The diagnostic problems of mentally handicapped patients are somewhat analogous to those of pre-pubertal children, in whom the DST has proved a useful diagnostic aid (Poznanski *et al*, 1982). This paper is the first report of the use of the DST in mentally handicapped patients.

Laboratory tests must be validated against clinical criteria, but the research instruments widely used for this purpose in affective disorders research—such as the Hamilton Rating Scale for Depression (HAMD) (Hamilton, 1967) and the Newcastle Diagnostic Index (NDI) (Carney *et al*, 1965)—have themselves rarely, if ever, been applied to mentally handicapped subjects (Matson, 1982; Kazdin *et al*, 1983; Russell & Tanguay, 1981; Ballinger *et al*, 1975). The same is true of the more recently introduced operationalised diagnostic criteria, notably the Research Diagnostic Criteria (RDC) (Spitzer *et al*, 1978): a recent literature review (Sovner & Hurley, 1983) could find no reports of the RDC being applied to mentally handicapped depressives. Thus idiosyncratic methodology may help to account for the disparate results of psychiatric

surveys in this field (Wright, 1982). The applicability of these research instruments and of the widely used International Classification of Diseases (ICD) (World Health Organisation, 1978) is also evaluated in this paper.

Method

The group studied was a consecutive series of patients referred for assessment of possible depression to psychiatrists attached to the Section of Psychiatry of Mental Handicap, St George's Hospital Medical School, which serves four Health Districts. Referrals were mostly from nursing and adult training centre staff: none were from general practitioners. There were 12 patients eligible for the DST, nine males and three females; eight were resident in hospital and the rest in the community. None required psychiatric admission as a result of the depression.

The DST was administered as part of the standard psychiatric assessment of depression. Informed consent was obtained from the patient where possible; otherwise, it was obtained from the next-of-kin, or from the care-giver when the next-of-kin was not in contact with the patient.

Exclusion criteria were as set out by Carroll *et al* (1981, 1982): temporal lobe epilepsy, hepatic enzyme induction by phenytoin and barbiturates, and high doses of benzodiazepines were of particular importance in mentally handicapped patients. Following a report of the induction of hepatic enzymes by carbamazepine (Privitera *et al*, 1982), patients on this drug were also excluded.

The dosage and timing of the test were in accordance with the procedure described by Coppen *et al* (1983): dexamethasone (1 mg) was given orally to the patient at 2000 hours, the author telephoning to confirm this before 2030 hours. A blood sample was obtained by 1530 hours the following day, and plasma cortisol estimated by radioimmunoassay. Laboratory staff were blind to the clinical ratings. A cortisol level of greater than 5 µg/dl was taken as an abnormal result.

All patients were classified according to the RDC and the glossary of mental disorders in the ninth revision of the ICD. Ratings were also made on the HAMD and the NDI. The ratings were made exclusively on data obtained directly from the patient and from a close informant; this was sometimes a parent and sometimes nursing or hostel staff. Historical data were obtained from clinical records.

Results

Patients

Some characteristics of the subjects are shown in Table I. The degree of handicap varied, from five patients at one extreme (cases 1, 7, 8, 9 and 11) who had not acquired verbal communication to three at the other (cases 5, 6 and 12) whose IQs were within the normal range, but who were included as they had been referred to psychiatrists in the mental handicap services, were resident in a mental handicap hospital (case 6) or hostel (cases 5 and 12), and had always functioned at levels much lower than might have been suggested by their IQs. Cases 3 and 11 had Down's syndrome, and birth trauma was probably responsible for the mental handicap of case 4, who had been born after a long labour and forceps delivery and also suffered from athetoid cerebral palsy. Only one patient (case 9) showed autistic features.

DST

Eleven of the twelve patients were effective suppressors of cortisol production, with post-dexamethasone cortisol levels below 5 µg/dl. One of the four major depressives (case 4) was the only non-suppressor, with a level of 13.5 µg/dl (Table I). There was no correlation of cortisol levels with severity of depression or endogeneity, as measured by the HAMD and NDI respectively.

The importance of the exclusion criteria was highlighted by one patient on carbamazepine, who was given the DST but was withdrawn from the study when a paper appeared demonstrating that carbamazepine produces false positive DST results (Privitera *et al*, 1982): he had a plasma cortisol of 15.1 µg/dl.

RDC

Four of the twelve patients had major depressive disorder, one of these carrying a 'definite' diagnosis. Seven further patients had minor depressive disorder, six of these being 'definite' and one 'probable'. The remaining patient fulfilled the criteria for 'probably currently not mentally ill'.

Two of the symptoms in the checklist for major depressive disorder occurred in only one patient (case 2); these were 'feelings of self-reproach or excessive or inappropriate guilt' and 'recurrent thoughts of death or suicide or any suicidal behaviour'. Apart from suicidal behaviour, these symptoms were found impossible to rate with any degree of conviction in the non-verbal patients. Four symptoms from the checklist are required for the diagnosis of 'probable' major depressive disorder and five for 'definite'; as it was feasible

to rate only six out of the eight possible symptoms in the non-verbal patients, their diagnoses were reviewed using the more lenient criteria allowed by the RDC for past episodes, with only three and four symptoms required to achieve probable and definite diagnoses respectively. The consequence was to convert cases 7 and 9 from definite minor to probable major depressive disorder, bringing the total of major depressives to six—a number which might have been expected to yield several positive DSTs if results in non-handicapped depressives had been applicable.

The RDC allows distinction between various subtypes of major depressive disorder: all four major depressives had primary rather than secondary disorder, three of them having had no signs of other psychiatric disturbance in the past year ('simple' subtype) as far as could be ascertained from the case notes: two were classified as probably endogenous and one as retarded. None of the depressions were secondary, recurrent, incapacitating, agitated, or situational.

ICD

Eight patients were classified as having a manic depressive psychosis category (296), two had adjustment reactions (309) to bereavement, and one could only be classified as 'depressive disorder not elsewhere coded' (311). The remaining patient had no affective disorder, but on the basis of the case history was thought to have an explosive personality disorder (301.3). No cases of neurotic depression (300.4) were found.

NDI

The mean diagnostic index was 5.3, and three out of the twelve scored above the 'endogenous' threshold of 5. The items of the index were then analysed individually. No patients scored positively on the items 'nihilistic delusions' or 'blames others'.

HAMD

Scores were calculated for the sum of the first 17 items of the scale, producing a mean score of 11.3 (Table I). The individual items with the lowest scores were psychic and somatic anxiety, gastrointestinal and genital symptoms, and hypochondriasis. It is possible that the lower scores were due to a genuinely lower level of symptomatology, but positive scores on these particular symptoms rely heavily on verbal report, and it seems more likely that the low verbal ability of this group of patients has artificially depressed the scores. Elimination of these symptoms (items 10, 11, 12, 14 and 15), together with two wholly verbal symptoms, 'guilt' and 'insight' (items 2 and 17), leaves ten items applicable to patients with any degree of mental handicap. It should be noted, however, that low scores on two of the remaining items ('suicide' and 'work and activities') also rely on verbal report and cannot be elicited by observation. Doubts must also exist as to the inclusion in the full rating scale of 'depersonalisation and derealisation', on which no mentally handicapped patient scored positively; this item is not required for the 17 item total.

TABLE
Clinical assessments and cortisol concentrations

Case No.	Age, years	Sex	Intelligence (most recent test), IQ	RDC ²	Diagnosis of affective disorder ICD-9	Raw	HAMD Adjusted	NDI	Plasma cortisol: $\mu\text{g/dl}$
1	17	M	40	Major (D)	Manic-depressive psychosis, depressed type (296.1)	13	19	8	1.5
2	19	M	58	Major (P)	Manic-depressive psychosis, depressed type (296.1)	15	17	5	0.9
3	30	M	49	Major (P)	Manic-depressive psychosis, depressed type (296.1)	8	14	5	<0.4
4	37	M	65	Major (P)	Manic-depressive psychosis, depressed type (296.1)	12	19	5	13.5
5	24	M	79	Minor (P)	Manic-depressive psychosis, circular type but currently depressed (296.3)	9	12	7	<0.4
6	26	M	78	Minor (D)	Manic-depressive psychosis, depressed type (296.1)	10	16	5	1.5
7	30	F	(MA < 1 year) ¹	Minor (D)	Depressive disorder, not elsewhere coded (311)	17	26	8	2.5
8	30	F	(MA = 2½ years)	Minor (D)	Adjustment reaction with mixed disturbance of emotion and conduct (309.4)	12	21	5	<0.4
9	35	M	(MA = 1½ years)	Minor (D)	Manic-depressive psychosis, depressed type (296.1)	8	12	5	1.3
10	37	F	43	Minor (D)	Manic-depressive psychosis, depressed type (296.1)	12	14	5	3.8
11	49	M	(MA = 3 years)	Minor (D)	Brief adjustment reaction (309.0)	10	12	4	0.9
12	20	M	84	CNMI (P)	Explosive personality disorder (301.3)	9	10	1	0.8

1 MA = Mental age

2. Major = Major depressive disorder; minor = minor depressive disorder; D = definite; P = probable; CNMI = currently not mentally ill

To obtain a Hamilton total comparable to that using the standard 17 items, the sum of the scores on the ten remaining items (items 1, 3-9, 13 and 16) must be scaled up by a factor of 1.73. The adjusted total scores are given in Table I: the corrected mean total is 16.0, nearly 5 points higher than the raw mean total. Correlation of the corrected totals with plasma cortisol levels was poor ($r=0.26$, $P=0.4$), but correlation with the NDI was high ($r=0.62$, $P<0.05$).

Discussion

As the patterns of care of mentally handicapped people change, more referrals to psychiatrists now originate from community nurses and other paramedical personnel on community mental handicap teams; without the general practitioner 'filter' between the community and the out-patient psychiatric clinic it would seem likely that milder and less intractable cases will be seen by the psychiatrist. This is confirmed by the present data, which reveal a generally mild level of depression, comparable with that treated in general practice (Sireling *et al.*, 1985).

The only positive DST was found in one of the patients with major depression. The sample size was small, but more non-suppressors might have been expected: giving the DST to patients with senile dementia, Spar & Gerner (1982) found that nearly half of those without major depression were non-suppressors. Although there were no false positives and the test was acceptable to patients, families, and care-givers, the DST seems to have little to offer in the differential diagnosis of depression in mentally handicapped patients. The reasons for this finding are not clear, and replication on a larger sample is required.

So far as the RDC are concerned, the excess of minor depression compared with major depression in this cohort is probably an artefact, resulting from the nature of several of the symptoms in the checklist for major depressive disorder. The requirements appear particularly stringent for non-verbal patients, and application of the 'past episode' criteria may give diagnoses more equivalent to those in non-handicapped subjects.

Rating the subtypes of major depressive disorder also presents difficulties in the mentally handicapped patient: in the present study, neither the memories of the patients nor the case notes were adequate to make decisions about the primary, secondary, or recurrent nature of the disorder. The criterion for a rating of 'incapacitated' is "inability to carry out any relatively complex goal-directed activity, because of severity of depressive symptoms", and this clearly is inapplicable to the more handicapped patient. Similarly, the subtype 'psychotic' requires the presence of delusions

or hallucinations—both hard to elicit in non-verbal patients—and four of the five manifestations of 'retarded' major depression depend on the presence of speech: this accounts for the discrepancy between the rarity of this subtype in the present cohort and the significantly greater degree of retardation, rated on the HAMD, and of depressive psychomotor activity rated on the NDI. Similar criticisms apply to the other subtypes of major depressive disorder, so that in general it is not feasible to rate any subtype except 'situational' in the non-verbal mentally handicapped patient.

The ICD glossary defining the rubric 'manic depressive psychosis, depressed type' (296.1) can be applied to patients with any level of mental handicap, as almost all the features described can be observed rather than elicited verbally. In contrast, the glossary for 'neurotic depression' (300.4), which was not identified in this cohort, is more difficult to apply, as it relies on terms such as 'disproportionate depression' and 'preoccupation with the psychic trauma', which are difficult enough to assess even in the absence of mental handicap.

The high proportion of 'endogenous' patients on the NDI could be due to selective bias on the part of those referring mentally handicapped patients to psychiatrists: such patients rarely present with complaints of dysphoria, and suspicion of a depressive condition may only be aroused when symptoms such as depressive psychomotor activity occur. Certain items of the NDI present problems of scoring in mentally handicapped patients, e.g. 'nihilistic delusions', 'guilt', and 'blames others for illness'; its validity must be doubted under these circumstances.

The more objective items of the HAMD such as sleep, weight loss, and effect on work and activities were readily rated, as was depressed mood, and this supports the clinical relevance of the adjusted Hamilton total score with the items dependent on verbal ability omitted. However, the raw score may be preferable for mentally handicapped patients with adequate communication skills, because items such as 'guilt' which are excluded from the adjusted form may be found frequently among mentally handicapped patients who are able to report such feelings (Heaton-Ward, 1977). The problems relating to individual items have been discussed, and the probable effect of selective referral bias can be seen here, as in the NDI, in the excess of retardation and the relatively low level of reported anxiety, somatic, and genital symptoms. Kazdin *et al.* (1983), who asked informants to complete the HAMD on 110 mentally handicapped adults (almost all mildly or moderately handicapped), also found it a satisfactory measure, correlating well with self-report measures.

Adequate tests of the validity of the adjusted score must await the collection of a further sample.

It is therefore suggested that widely used research tools such as the RDC and HAMD can, with modifications, be applied to the entire range of mental handicap in the diagnosis of affective disorder and the measurement of its severity. However, the modifications must be specified and preferably standardised, so that studies will be comparable: this paper proposes certain modifications. Particular problems with the ICD-9 and the NDI render these instruments unreliable for use with mentally handicapped patients.

The possibility of applying such sensitive instruments to mentally handicapped patients would aid the evaluation of new psychiatric techniques such as the DST, and would facilitate the evaluation of treatment methods in mentally handicapped patients with affective disorders.

Acknowledgements

I am grateful to the patients, the staff of Normansfield Hospital, the Richmond and Kingston Community Mental Handicap Teams, Dr B. W. Meade, Mrs Kath Matthews, and Professors D. J. Bicknell and E. S. Paykel.

Emotional Attitudes and Direct Communication in the Families of Schizophrenics: A Cross-National Replication

A. M. STRACHAN, J. P. LEFF, M. J. GOLDSTEIN, J. A. DOANE and C. BURTT

To examine how the measure of expressed emotion relates to family life, 30 relatives of schizophrenic patients were assessed for EE and then observed in ten-minute discussions with the patients. It was found that high-EE relatives express more negative emotional statements than low-EE relatives when face-to-face with the patient; they also talk more rapidly, and this speech rate is correlated with the patient speech rate. Whereas low-EE relatives expressed few criticisms or intrusive statements, high-EE over-involved relatives were more intrusive, and high-EE critical relatives were more critical as well as more intrusive in direct interaction. These findings emphasise the importance of understanding divergent EE sub-styles and the complementary behaviour of patients. The findings of an earlier Los Angeles study were replicated.

Over the last decade, evidence has been accumulating that the family emotional atmosphere to which schizophrenic patients return from hospital, as indexed by expressed emotion (EE), critically affects the likelihood of relapse from schizophrenia (Vaughn & Leff, 1976a; Leff & Vaughn, 1981; Vaughn *et al.*, 1984), and that interventions directed at changing EE reduce this risk (Leff *et al.*, 1982, 1985).

In another experimental trial, Falloon *et al.* (1985) have shown that psychosocial interventions, aimed at improving communication skills and problem-solving behaviour in families at risk, reduce the likelihood of relapse and improve the patient's social functioning. These changes are significantly related to the style of direct affective expression, as indexed by affective style (AS) (Doane *et al.*, 1985, 1986).

Most recently, Hogarty *et al.* (in press) examined the additive effect of two different treatment methods to maintenance antipsychotic medication: psycho-educational family treatment and individual social skills training. Of the 90 patients who stayed in treatment, the medication comparison group had a relapse rate of 41%, whereas the group that received both family and social skills training had a relapse rate of 0%, at one year follow-up. Furthermore, from measurements of EE at intake and one year follow-up, Hogarty *et al.* found that there were no patient relapses in any household that changed from high to low EE independent of treatment; in households that stayed high EE, only the combination of family therapy and social skills training prevented relapse.

Thus, both naturalistic and treatment studies suggest the importance of EE and AS as key indices of family processes. The primary aim of the current study was to examine the relationship between these two measures, to see how EE attitudes were expressed in direct interaction with the patient. It focused particularly on the differences between high-EE relatives with critical and over-involved attitudes.

Previous studies of the interactional correlates of EE attitudes in relatives of schizophrenics have assessed direct communication by a relative to a patient, but only in the presence of an interviewer (Kuipers *et al.*, 1983) or a second relative (Miklowitz *et al.*, 1984). It is possible, however, that the presence of others can suppress the expression of high-EE attitudes. For instance, one parent in a triadic discussion may dominate the discussion such that the other parent says very little, thus making it difficult to assess their individual styles of emotional expression. Alternatively, the presence of another relative can modify the way they express themselves to the patient. For instance, Valone *et al.* (1983) studied the correlates of EE in dyadic and triadic interactions between parents and their non-schizophrenic adolescent offspring. They found that parents often altered the number and harshness of their criticisms when interacting with their child in the presence of their spouse compared with their behaviour when alone with the offspring. The current study overcomes such problems, by studying dyadic communication between patient and relative.

A second aim of the current study was to compare

the expression of emotional attitudes in Britain and the United States. The recent cross-national replication of the British relapse studies (Vaughn *et al*, 1984) demonstrated that relapse in a US sample was predicted by similar levels of criticism and emotional over-involvement as found in the earlier British studies, suggesting that the attitudes of relatives have a similar impact on patients in the two countries.

However, this still leaves the question of whether the crucial mediating mechanism of intrafamilial behaviour is comparable in samples from the two countries. Miklowitz *et al* (1984) demonstrated a correspondence in a US sample between EE and AS, finding that relatives with critical attitudes were more critical in direct interaction and relatives with over-involved attitudes were more intrusive. However, because of different cultural norms in the expression of emotion, it may be that the overt expression of attitudes, particularly negative ones towards one's offspring or spouse, varies from country to country. We aimed to compare results from this British sample with data from previous US studies of EE correlates, to determine whether such cross-national variations exist.

Method

Participants

The sample was selected from recent admissions to Friern Hospital, a psychiatric hospital in North London. All files of patients admitted to acute admission wards were reviewed regularly for two years. Patients were selected for screening if: (a) they had lived with a partner or one or both parents for at least one month out of the previous three, (b) they were likely to be diagnosed as having schizophrenia, and (c) they had been admitted for the first time within two years of the current admission date. Patients were excluded if they showed evidence of an organic brain syndrome, or significant alcohol or drug abuse.

Prospective participants were given the Present State Examination (PSE). The clinicians had been previously trained to reliability on the rating of symptoms. All patients were interviewed within the first few weeks of admission (median = 12 days). If patients met criteria for a positive diagnosis of schizophrenia according to the PSE, the relatives were asked if they would consent to participate in the study. There were two exceptions, each of whom had one first-rank symptom which would have led to a positive diagnosis of schizophrenia according to the CATEGO program, but who presented a clinical picture of a manic psychosis; these were excluded from the trial. Of the sample of 24 patients who passed these initial screening procedures, one set of parents refused, and one family was not approached because it was already too involved with mental health services. The remaining 22 families agreed to participate. There were no further drop-outs from the study.

Of the 22 patients with a positive diagnosis of schizophrenia who were included, 21 met CATEGO criteria for schizophrenia on the basis of the presence of first-rank symptoms from Schneider's 'nuclear syndrome' of schizophrenia. The other participant showed delusions and auditory hallucinations, which fit the CATEGO criteria for 'paranoid psychosis.'

Additional historical data, independently collected, enabled diagnoses to be made on the basis of DSM-III (American Psychiatric Association, 1980). All of the patients satisfied criteria for a diagnosis of schizophrenia except one, whose symptom pattern suggested the possibility of a schizo-affective disorder.

The sample was from a relatively acute psychiatric population. This was the first admission for 59% of the sample, and the mean number of previous admissions was 0.73 (*s.d.* = 1.24), all of which had occurred within the previous two years. Most had lived continuously with their close relatives for the previous three months: a mean of 85 days out of 90 (*s.d.* = 16 days).

The sample was heterogeneous for age, gender, ethnicity, and socio-economic status: 8 were female and 14 male; 12 were British caucasians, 5 West Indian, 3 continental European, and 2 of mixed ethnic origin. The mean socio-economic status was 'unskilled' according to the UK Registrar General's classification (Office of Population Censuses and Surveys, 1980). Some had been students or had semi-skilled jobs prior to admission, but most were unemployed: the mean length of unemployment was 12 months out of the previous 24 (*s.d.* = 10 months). The mean age was 24.6 years, ranging from 18 to 51. The two oldest patients had experienced long-standing encapsulated delusions, but the families and patients had adapted to these with few problems, and they had not sought psychiatric treatment. They were admitted to hospital only when other psychotic symptoms appeared.

Medication levels were obtained from charts and converted to chlorpromazine dose equivalents (Davis, 1976). The mean dose at the time of the initial PSE was 371 mg, and at the time of the direct interaction task was 328 mg.

The 30 relatives had a wide range of socio-economic statuses: the mean occupational level was social class III (M), 'skilled manual workers', which was higher than that of the patients. Most of the relatives were parents: eight patients lived with both parents, eight lived alone with their mothers, and two alone with their fathers. Four patients lived with a partner: three with husbands and one with a wife. The mean age of the relatives was 50.2 years, ranging from 28-71 years.

Camberwell Family Interview

To elicit and measure EE attitudes, key relatives were administered the modified Camberwell Family Interview (CFI) according to the procedures of Vaughn & Leff (1976b). This interview was conducted at home, while the patient was in hospital, it was administered separately to each relative, a median of 26 days after intake.

The tapes were rated by clinicians extensively trained at the Institute of Psychiatry to rate EE; most were rated by two people. Five aspects of the relative's attitude were assessed: the number of critical comments (CC), the number

of positive remarks, the presence or absence of hostility, and ratings of emotional over-involvement (EOI) and warmth on six-point scales. A sample group of tapes classified by two raters into high and low EE showed agreement for 12 of the 13 tapes. Individual scale Pearson product-moment correlations were as follows: CC, $r=0.86$ ($P<0.01$); EOI, $r=0.94$ ($P<0.01$); hostility, $r=0.67$ ($P<0.02$). A further seven tapes which were rated by two raters for warmth and positive remarks had Pearson correlations of 0.74 ($P<0.05$) and 0.86 ($P<0.01$) respectively.

Classification

Relatives were classified as high EE if they made six or more critical comments or had a rating of three (moderately high) or more on emotional over-involvement. All other relatives were classified as low EE. These criteria are the same as used in recent EE research (Leff *et al.*, 1985; Miklowitz *et al.*, 1984). Using these criteria, 23 relatives were classified as high EE and 7 as low EE. This is a higher proportion of high-EE relatives than was reported in Camberwell (Vaughn & Leff, 1976a) and may reflect subculture variation.

The high-EE group was further divided into three subgroups:

- (a) critical group ($n=14$): those relatives scoring high on CC but low on EOI (using the same criteria as above)
- (b) emotionally over-involved group ($n=5$): those relatives high on EOI but low on CC
- (c) critical and emotionally over-involved group ($n=4$): those relatives high on both CC and EOI.

Ten relatives were rated as showing hostility; in every case they also made six or more CCs, confirming previous work (Vaughn & Leff, 1976a).

Relatives' EE status was examined in relation to family type. There were no significant differences in the percentages of low and high-EE relatives among single-parent, dual-parent, and spousal family units, and none in the percentages of low and high-EE relatives between mothers and fathers. There were also no significant differences across the EE subgroups. It was observed, however, that seven out of nine relatives with high EOI scores were mothers. The distribution of the four spouses across the EE categories did not differ markedly from the distribution of parents: one was low EE and three were high EE, two of these being critical and one emotionally over-involved.

Because eight patients were living with more than one key relative, a second classification was used for analyses by family unit rather than by individual relatives. If both parents were low EE, the family was considered dual low EE ($n=4$); if one was high EE and the others low EE, the family was considered mixed EE ($n=3$); if both were high EE, the family was considered dual high EE ($n=15$). All family units, whether of one or two relatives, could thus be classified as uniformly low, uniformly high, or mixed EE.

To determine whether there were differences in EE which related to characteristics of the sample, demographic variables were compared between high EE and low combined with mixed EE families. There were no differences for any of these variables.

Direct family interaction procedures

After the individual assessment of patient and relatives, a meeting was convened to assess face-to-face family interactions. This usually took place shortly before the patient was discharged, and was usually in the hospital, but sometimes at home. The median length of hospital stay was 42 days, and the median time to the interaction meeting 40 days.

The direct interactional task was a discussion between the patient and each relative separately about an issue of conflict, further details of the procedure are described in Miklowitz *et al.* (1984). The relative and patient were left to discuss the issue on their own, while the research worker monitored the conversation from another room and returned after ten minutes. The researcher would only return before that time if conversation stopped. Another topic would then be introduced, until a total of ten minutes' discussion had taken place. Whether the relative or patient cue was used as the first stimulus was randomised.

Immediately after these discussions, the clinician held a short debriefing session to answer questions, and to defuse any conflicts which might have arisen.

Direct interaction coding

Transcripts of the interactions were made and checked carefully before being sent to the UCLA Family Project for coding. A critical incident system of coding—the affective style (AS) coding scheme (Doane *et al.*, 1981)—was used. These codes are defined briefly below.

Benign criticisms are circumscribed, matter-of-fact, or directed towards specific incidents or sets of behaviour.

Harsh criticisms is a category made up of several sub-categories: 'Personal criticisms', in which criticism is made of broad classes of behaviour, or the patient's basic negative character; 'Guilt induction', in which the relative conveys that the patient is to blame for some event which has distressed the relative, and 'Critical intrusiveness', in which the relative implies knowledge of the patient's internal states and is critical of his intentions.

Neutrally-intrusive statements imply knowledge of the patient's emotional states, ideas, or preferences when there is no apparent basis for such knowledge (e.g. "You went out for a drink because you were upset."). These statements are neutral in tone, and do not imply criticism, but might be experienced by patients as intrusive and stressful.

Support the relative conveys that he or she feels genuine concern for the patient or about the patient's problems or behaviour, or supports the patient in other ways (e.g. "I know of nobody who makes more of an impression on others than you do.").

Reliability

The interaction transcripts were coded by two coders, blind to EE status. Inter-rater reliability was established prior to the present study on a sample of 27 transcripts from an earlier study of families containing a nonpsychotic adolescent, it was highly significant for benign criticisms ($k=0.85$, $P<0.0001$), harsh criticisms ($k=0.89$, $P<0.0001$),

neutral-intrusive statements ($k=0.85$, $P<0.0001$), and support ($k=0.86$, $P<0.0001$).

AS profile patterns

In addition to analyses of means, analyses were made on a case-by-case basis, and a profile method was designed to parallel the EE profiles. Previous studies have assigned a negative AS profile to relatives who express six or more neutral intrusions or one or more personal criticisms, guilt-inductions, or critical intrusions (e.g. Doane *et al*, 1985). However, intrusive profiles and critical profiles have not been separately defined. Since Valone *et al* (1983) showed that benign criticisms also were related to high-EE attitudes, relatives were assigned a 'critical' AS profile if they had at least one personal criticism or an excessive use (six or more) of the less impactful code of benign criticisms. They were assigned as 'intrusive' AS profile if they had at least one guilt induction code (which has an intrusive quality) or an excessive use (six or more) of the less impactful code of neutral intrusions. Some relatives met both criteria; those who met neither were assigned a 'good' AS profile.

Referrals

Eleven high-EE families were subsequently included in a randomised trial of educational, pharmacological, and psycho-social interventions, comparing a group for relatives with in-home family therapy. However, all data for the current study were collected prior to any intervention.

Results

Expressed emotion and affective style

The main aim of this study was to examine the relationship between emotional attitudes expressed about a patient to a neutral interviewer and direct emotional communication with that patient. It was hypothesised that high-EE relatives would be more emotionally negative than low-EE relatives—critical, intrusive, or both—when face-to-face with the patient. Table I shows the number of different

TABLE I
Means and standard deviations for high and low-EE interactions: affective style scores and speech rates

Affective style	Low EE		High EE	
	Mean	s.d.	Mean	s.d.
Criticism	0.86	1.86	5.00	5.21
Neutral intrusions	3.86	3.76	6.26	4.95
Total negative AS	4.71	5.47	11.26	7.71
Support	2.71	3.55	0.65	1.15
Relative speech rate	43.0	20.9	70.8	35.0
Patient speech rate	22.0	12.8	35.7	19.5
Total speech rate	65.0	27.0	106.5	46.7
Speech turnovers	72.0	45.3	94.5	44.2

affective style codes, as well as the total number of negative codes, used in ten minutes of interaction. For each analysis a two-tailed *t*-test was used. Variances were pooled unless they were significantly different, in which case a separate variance estimate was used.

High-EE relatives expressed significantly more negative AS statements in total than low-EE relatives ($n=30$, $t=2.08$, $P<0.05$). Breaking down the negative AS total score into criticisms and intrusions, high-EE relatives made significantly more criticisms than low-EE relatives ($n=30$, $t=3.20$, $P<0.003$). This was so regardless of whether the low frequency harsh criticisms were included in the total score. There was a trend for high-EE relatives to make more neutrally intrusive statements and fewer supportive statements, but neither trend reached statistical significance.

Expressed emotion and speech patterns

The relationship between EE and speech patterns during the interaction was examined. The number of words used by relatives during the ten minutes of interaction was measured from the number of lines on the verbatim transcript. High-EE relatives used a significantly greater number of words (65% more) than low-EE relatives ($n=30$, $t=1.98$, $P<0.05$) (Table I). This could be due to a generally more heated interaction, or to the high-EE relative being more dominant and lecturing. Therefore, the number of words used by the patient was added into the analysis. A two-way analysis of variance was conducted with EE (high or low) as one factor and relationship (relative or patient) as the other (this factor was correlated because patient and relative were in the same interaction). There were significant effects of EE ($F=4.94$, d.f. = 1,28, $P<0.03$) and of relationship ($F=18.57$, d.f. = 1,28, $P<0.0002$), but the interaction was not significant. Relatives thus use significantly more words than patients (twice as many), and the total number of lines used in interactions which included high-EE relatives was significantly greater (64% more) than for low-EE relatives. Since all conversations were exactly ten minutes long, it can be concluded that the average rate of speech was significantly greater over the course of the conversation. Patients tended to use more words speaking to high-EE relatives than to low-EE relatives (62% more), the difference being comparable to that found between high and low-EE relatives. Furthermore, there was a significant and positive correlation between the relatives' word count and the patient's word count (Pearson's $r=0.47$, $P<0.004$). Interaction with a high-EE relative is thus characterised by high verbal activity on the part of both relative and patient.

To investigate the length of individual speeches, a count was also made of the number of turnovers (i.e. changes from one speaker to another) during the ten minutes. Although the mean for high-EE interactions was 31% larger, the difference was not significant. This suggests that high-EE interactions were not characterised by longer speeches, but had at least as many changes of speaker as low-EE interactions.

EE sub-categories and affective style

A second aim of this study was to examine how different

TABLE II
Mean AS scores for low-EE and high-EE subgroups of relatives

Affective Style	Low EE	Critical	EOI	Critical and EOI
Criticism				
Mean	0.86	6.14	2.40	4.75
s.d.	1.86	5.79	1.52	6.18
Neutral intrusions				
Mean	3.86	5.57	6.20	8.75
s.d.	3.76	4.72	4.97	6.07

kinds of high-EE attitudes (criticism and EOI) would be expressed in direct interactional behaviour with the patient. It was hypothesised that a critical attitude would be seen as direct criticism of the patient and an emotionally over-involved attitude would correlate with neutral intrusions in the interaction. To examine this, an analysis of variance (ANOVA) was performed on the four sub-categories of EE: low, high on critical comments only, high on EOI only, and high on both EOI and critical comments.

It was found, as expected, that differences among the three high-EE sub-groups would not be significant for total AS, support, and rate of speech. Thus, all three high-EE sub-groups of relatives were consistently higher than low-EE relatives on total AS and rate of speech. Previous analysis had shown no mean differences between high and low-EE relatives on weekly face-to-face contact. However, there were found to be significant differences between sub-groups ($n=30$, d.f.=3, $F=2.96$, $P<0.05$), with the pure high-EOI relatives spending far more time (61 hours) with the patients than other kinds of relatives (26 hours).

As predicted, when the negative AS codes were broken down into their components of criticisms and neutrally intrusive statements, a more complex pattern emerged (Table II). All relatives who scored highly on CC (i.e. the high-EE critical and the high-EE critical + EOI subgroups combined) were compared in planned contrasts (on the basis of Miklowitz *et al.*, 1984) with the other two subgroups. The combined high-CC group made significantly more criticisms in direct interaction than both the low-EE group ($n=25$, $t=3.27$, $P<0.01$) and the purely high-EOI group ($n=23$, $t=2.27$, $P<0.05$).

Similarly, for the analysis of neutrally intrusive statements, the combined high-EOI groups were compared in planned contrasts with the other two sub-groups. The combined high-EOI group did not make significantly more neutral intrusions than the low-EE group ($n=16$, $F=2.25$, NS) or the purely high-CC group ($n=23$, $F=0.87$, NS), although the pattern of means was as expected.

The pattern of means for criticisms and intrusive statements in this British sample (Fig. 1) closely follows that seen in the American sample reported by Miklowitz *et al.* (1984), and replicates their findings.

However, although the findings for total criticisms are quite clear-cut, the pattern of means for neutrally-intrusive

statements is not so clear. Specifically, the mean number of neutral intrusions made by the high-EE critical subgroup is about the same as the mean number made by the high-EE EOI subgroup. In order to assess what this means about the way critical attitudes are displayed in direct interaction, correlational and case-by-case profile analyses were performed.

Firstly, the correlation between the number of critical statements and the number of neutrally intrusive statements was not significant ($n=30$, Pearson's $r=0.20$, NS). Secondly, the correlation between EOI (scored dichotomously as high or low) and neutral intrusions was marginally significant ($n=30$, Pearson's $r=0.24$, $P<0.10$) as predicted, whereas the correlation with total criticisms was not. However, the correlations between critical attitudes shown in the CFI interview and critical comments and neutral intrusions in direct interaction were both significant (criticism: $r=0.32$, $P<0.05$, neutral intrusions: $r=0.31$; $n=30$, $P<0.05$). This suggests that critical attitudes may be displayed in direct interaction as both criticism and intrusive statements, whereas emotional over-involvement may be displayed as neutral intrusions only.

This hypothesis is confirmed by case-by-case analyses, using the profile analysis described under 'Method'. Six of the seven low-EE relatives had good AS profiles, and 18 of the 23 high-EE relatives had critical or intrusive profiles—a highly significant difference (Fisher's exact $P<0.004$). Examining these data in greater detail, there is a significant overall skew in the data ($\chi^2=19.5$, d.f.=9, $P<0.05$), because relatives who are EOI in attitude (regardless of whether they are also critical) tend to be intrusive in interaction (six out of nine), and the majority of relatives who are critical in attitude tend to be either critical in behaviour or critical and intrusive in behaviour (8 out of 14).

Analysis of means, correlations, and case-by-case profiles therefore point to the same conclusion: that emotionally over-involved relatives display neutrally intrusive statements in face-to-face interactions, whereas critical relatives display both criticisms and intrusions.

Patient measures and EE

To determine whether the differences in relatives' attitudes towards the patient are related to differences in the

FIG. 1. Mean number of critical and intrusive statements made by relatives of schizophrenics with various EE attitudes

patient, we examined the relationship between relatives' EE and measures of premorbid socio-sexual functioning, medication levels and psychiatric state at intake.

The UCLA Social Attainment Survey was used as a measure of social-sexual competence prior to the onset of symptoms. Scores for patients from pure high-EE families were compared with those of patients from low and mixed-EE families. There were no significant differences, using either raw scores or the sex-specific criteria for defining good and poor premorbid status (Goldstein, 1978). There were also no significant differences in medication levels at the time of the PSE or at the direct interaction.

The PSE symptoms were grouped into the 38 CATEGO syndrome clusters (Wing *et al.*, 1974). A syndrome was considered present when the patient received a positive rating (1 or 2) on any symptom which was part of the cluster. The presence or absence of syndromes was examined in relation to the family EE status, comparing high-EE families with low and mixed-EE families combined. There were no significant differences in the proportion of patients who had any one syndrome present, but there were trends for syndromes related to depression. The four syndromes related to depression were therefore examined: depressive delusions and hallucinations, simple depression, special features of depression, and other symptoms of depression. It was found that only two out of the seven patients from the low or mixed-EE families had more than one syndrome of depression, whereas 11 out of the 15 patients from high-EE families had more than one syndrome of depression. This was a significant difference (Fisher's exact $P=0.05$). Furthermore, the presence of irritability was related to depression ($P<0.05$), although it did not reach significance

in relation to EE. These data may reflect a greater emotional reactivity to high-EE relatives in recent-onset schizophrenic patients, or stronger emotional responses by relatives to patients with a depressive aspect to their condition.

Family type

To investigate whether parents behaved differently from spouses, two-way ANOVAs were performed with family type as one factor, level of EE as the other, and EE and AS scales as dependent variables. The only significant differences were for spouses to show greater warmth in their attitude to relatives ($n=30$, d.f.=1, $F=7.71$, $P<0.01$) and more face-to-face contact ($n=30$, d.f.=1, $F=4.09$, $P<0.05$). There were no significant interactions, and thus it can be concluded that the relationship between emotional attitudes and behaviour is consistent across family types.

Discussion

This study examined how relatives of schizophrenics display EE attitudes in direct interaction with patients in a dyadic situation without the confounding presence of other relatives or clinicians. During a ten minute behavioural sample of dyadic communication between relative and patient about a conflictual issue, high-EE relatives were more affectively negative than low-EE relatives, being more critical, guilt-inducing, or intrusive. Such a negative emotional family climate is likely to be stressful, and appears to increase the risk of the development of schizophrenia-spectrum

disorders (Doane *et al*, 1981; Goldstein, 1985) as well as the risk of a relapse in someone recovering from an episode of schizophrenia (Doane *et al*, 1985; Vaughn & Leff, 1976a; Vaughn *et al*, 1984). Furthermore, changes in the affective climate of the family may decrease the risk of a relapse, as several recent family intervention studies have suggested (Strachan, 1985; in press).

Relatives who had EOI attitudes tended to be intrusive when face-to-face with the patient, either by making an excessive number of statements implying knowledge of what was going on in the patient's mind, or by making one or more guilt-inducing statements which blamed the patient for causing problems to the relative and implied that the patient had malicious or at least uncaring intentions. The picture was more complicated for relatives with highly critical attitudes. They were clearly more critical when face-to-face with the patient, by making either an excessive number of relatively benign criticisms or one or more statements which were harshly critical and attacked the character of the patient. However, it also appeared that relatives with a critical attitude were more intrusive as well. That high-EE critical and high-EE EOI relatives both use neutral intrusions in direct interaction raises the question as to whether the neutral intrusions used by high-EE critical relatives are different in type and impact from neutral intrusions used by high-EE EOI relatives or low-EE relatives. Research into this question is in progress.

Overall, these data closely parallel the pattern of findings of the connection between EE and interactional behaviour described by Miklowitz *et al* (1984), despite several differences in procedure and analysis between the two studies: we examined ten minutes of dyadic discussion without adjustment for line-length, whereas Miklowitz examined longer triadic discussions but adjusted them to control for word length. There is thus a comparability between intrafamilial behaviours in the UK and the USA, suggesting that family mechanisms mediating EE are comparable in the two countries.

A special aspect of the sample was that it was composed of recently admitted schizophrenics. Although most had suffered a recent onset of their symptoms, two patients had had longer-standing delusions. To assess whether these data were representative of a recent-onset sample, the main analyses were repeated excluding these two patients. Essentially similar results were obtained. Since the Miklowitz data were obtained from a more chronic population, this data thus appears to suggest that EE-AS relationships in a recent onset sample are similar to relationships in a more chronic sample.

It is important to note that while EE relates to the AS measure of interactional behaviour, the two measures are not identical in meaning. The EE measure taps emotional attitudes of the relative, whereas the AS measure taps direct interactional behaviour. The EOI measure in particular takes account of over-protective behaviour and excessive self-sacrifice, both of which are long term aspects of relatives' behaviour. That intrusiveness is associated with EOI does not mean they are identical, but the two are consistent in that intrusive remarks involve speaking for the patient, or making assumptions about his or her inner state.

Another important finding was that in high-EE pairs both relatives and patients used more words than was the case in low-EE pairs. Thus, in high-EE dyads, both participants are actively involved in the interaction, contradicting the thesis that high-EE relatives are dominant and the patients submissive. These data also argue against the idea that a negative affective style is merely a result of the high-EE relative being more dominant and speaking a higher proportion of time, thus producing more criticisms and intrusions. Furthermore, these data contradict the idea that a higher rate of negative behaviour is an artifact of word count: although high-EE relatives used 65% more words than low-EE relatives, they used more than twice as many intrusions and criticisms. It should be noted, however, that this pattern may change over the years if the patient becomes more chronic and withdrawn.

These findings relate to the study by Kuipers *et al* (1983), who observed relatives and patients talking to an interviewer, and found that high-EE relatives spent 57% more time talking than low-EE relatives—a figure close to the 64% higher word count observed here. They also found that the amount of silence was significantly greater in low-EE pairs than in high-EE pairs. They did not find that differences in the patients' behaviour were related to EE, but this may have been because an interviewer was present—this could inhibit the development of a reciprocal interaction pattern between the other two.

Do low-EE relatives show more support than high-EE relatives? The above studies showed no differences, but this may have been because the discussions were emotionally charged, thus eliciting critical and intrusive statements. There is evidence that with more neutral issues, low-EE relatives show more positive behaviours such as approval, agreement, smiling and humour (Greenwald *et al*, cited in Strachan *et al*, 1986).

Together, these studies suggest that interactions with high-EE relatives can be characterised as lively and heated, with a great deal of excitability, criti-

cisms, intrusiveness, interruptions, and simultaneous speech. Low-EE interaction can be characterised as calmer, more affectively neutral, more positive and supportive, and less verbal, with more pauses.

These findings also pose intriguing questions about patients' responses to, or provocation of, the criticisms and intrusions of the high-EE relative. Is the patient's style of coping one of counter-attack, withdrawal, or more differentiated expressions of autonomy? Are there repeated patterns of patients' behaviour which precede relatives' criticisms or intrusions? While the present study did not examine such issues, the word counts suggest that patients are actively involved in interactions with high-EE relatives, rather than being withdrawn.

The finding that patients with high-EE relatives reported more depression and irritability suggests hypotheses about the cyclical nature of the interaction. For example, Vaughn (1986) reported that the majority of critical comments are about long-standing attributes of the patient, rather than about recent changes in behaviour. As the current study suggests, this criticism of characteristics of the patient is probably expressed over the years and may, if internalised by the patient, contribute to the depressive symptomatology. Alternatively, as Coyne (1976a,b) has argued, the behaviour of depressed individuals may elicit alternating messages of rejection and reassurance. It is possible that patients who make self-deprecating remarks or statements of hopelessness elicit or perpetuate relatives' criticism and intrusiveness.

Thus, both the expression of high-EE attitudes

and the patients' depression and irritability may interact in a cyclical pattern. Further examination of patients' behaviour using sequential analyses could help to explain processes which might maintain and perpetuate a cycle of mutual antagonism or which might lead to a de-escalation of tensions. Such exploration might help to explain why, despite the general congruency between attitudes and behaviour shown in this study, there are discrepancies.

In conclusion, the establishment of a basic congruence between emotional attitudes and behaviour shown by these data in a British sample confirms the findings of Miklowitz and Valone in American samples. Taken together, the reports provide cross-national replications which parallel those of the relationship between EE and relapse in both Britain and the USA (Vaughn & Leff, 1976a; Vaughn *et al*, 1984), thus building a solid body of evidence on the nature of EE and suggesting that there are comparable behavioural mediating mechanisms in direct behaviour in the two countries.

Monitoring of Long-Term Motor Activity in Depressed Patients

S. ROYANT-PAROLA, A. A. BORBELY, I. TOBLER, O. BENOIT and D. WIDLÖCHER

Wrist motor activity was continuously recorded by a solid-state monitor in 12 patients with major depression throughout their stay in hospital; their clinical state was evaluated using three scales. During the day, activity troughs and immobility peaks occurred before noon and around 1500 hrs. Activity level progressively increased, while the duration of immobility decreased, with clinical improvement. The immobility measurement appeared to be a valuable index of depression and is more sensitive than the activity level, mainly for agitated depressed patients. Immobility episodes during the day could suggest the release of an ultradian sleep-wake rhythm in depression.

Changes in motor behaviour accompanying depressive illness have long been recognised. Psychomotor retardation or agitation are part of the criteria used for the diagnosis of major depression, together with other symptoms including anorexia, insomnia, lack of interest, and guilt. A distinction has been made between agitated and retarded depressions, but this is usually dependent on the presence or absence of motor retardation and does not take into account psychic retardation. It has also been maintained that retardation is almost always a sign of major depressive illness, and the classical description of melancholia has retained marked psychomotor retardation, which in some extreme cases may mimic stupor.

A global clinical scale to assess retardation has been proposed by Widlöcher (1983a, b), and includes both mental and motor components. There have been attempts to measure retardation using specific techniques such as the "speech pause time" test for verbal flow (Hardy *et al*, 1984), and other authors have tried to measure the motor component by means of telemetry (Kupfer *et al*, 1974; Post *et al*, 1977), or by using a small activity monitor (Kripke *et al*, 1978; Wehr *et al*, 1980, 1982; Borbely, 1983).

The main purpose of our study was to evaluate the extent to which objectively recorded motor activity parameters are correlated with the clinical state, as assessed by rating scales, during pharmacological treatment of depression.

Method

Patients

Wrist motor activity was continuously monitored in 12 depressed patients during their stay in a psychiatric ward; seven were also recorded for an additional week at home,

after discharge. All depressive patients admitted between 15 April and 15 May 1983 were considered for the study. To be included, they had to give informed consent and agree to the requirements of the study (principally the continuous wearing of a wrist monitor). The two who did not consent to these conditions were excluded. The remaining patients (ten females, two males) were classified as major unipolar depressives, according to DSM-III (American Psychiatric Association, 1980); by the Newcastle criteria (Gurney, 1971), six were considered endogenous depressives, four non-endogenous, and two 'doubtful'. In one patient a manic period occurred several months after the end of the study; this patient had been a night worker one month prior to her admission. The mean age was 55 (range 40-76 years), and the mean duration of hospital stay 31 days (range 15-71). Prior to admission, five patients had received antidepressive treatment for several weeks; in eight cases this included benzodiazepines. During admission, all the subjects received specific antidepressive therapy (the tricyclic compounds, mianserine and clenbuterol, alone or in combination) as well as benzodiazepines.

The activity monitor

Motor activity was recorded by a solid-state motor activity monitor (Borbely *et al*, 1981) which was worn like a wrist-watch on the non-dominant arm; this is small (30 × 51 × 17 mm) and light-weight (87 g). Movements were recorded by a piezo-electric transducer, which generates a pulse whenever acceleration exceeds a preset threshold (0.1 g). The pulses were counted during a preset time interval (15 min), and their number stored in a memory (storage capacity 256 h). The power was provided by three 1.5 V batteries.

Clinical evaluation

During the recording period, the clinical state was evaluated on four occasions: at admission, before starting the antidepressive treatment (day 0) and after a one week washout of the previous antidepressive drugs; eight days

after the start of antidepressive treatment (day 8); on the day before discharge (day D); and after one week at home (day H). These clinical evaluations were based on two global depressive symptomatological scales—the Hamilton depressive rating scale (HAMD) (Hamilton 1967) and the Montgomery and Åsberg Depression Rating Scale (MADRS) (Montgomery and Åsberg, 1979)—and on the depressive retardation rating scale of Widlöcher (1983a, b). The sleep-wake schedule, the extent of nocturnal awakenings, and the occurrence of naps were estimated from the sleep diaries kept by the patients.

In addition, subjects were asked to rate their mood six times per day (every 3 hours) on a visual analogue scale, anchored by the words "I am not feeling sad" and "I am feeling sad". Four patients were unable to perform the self-rating (three among them were the most severely depressed, with HAMD scores of 31, 29, and 28).

Analysis of data

Clinical improvement was expressed relative to the score obtained on admission. The criteria for remission were an improvement resulting both in a decrease of 10 points or more on the HAMD scale and in a score under 10: these criteria correspond roughly to an improvement of at least 60% relative to the entrance score.

The level of motor activity was analysed by 15-minute periods; the mean of the 15-minute values was calculated for each 24-hour period. On the days of clinical evaluation the data were averaged with those of the preceding and the following days to obtain more stable values. The number of 15-minute immobility epochs was calculated separately both for the day and night together and for the night alone (0000–0060 hrs). The hourly distribution of levels of both activity and immobility were calculated for the days of clinical evaluation.

The data were analysed by means of one way analysis of variance. Spearman rank correlations between clinical scores and motor parameters were computed.

Results

Table I gives the clinical evolution of the patients as a group. There was a relationship between improvement and a progressive decrease in the three clinical scores. A 17-day recording of motor activity is illustrated in Fig. 1, showing the nocturnal awakenings and occasional naps. However, daytime immobility periods did not always correspond to naps. Although no sleep recording was performed, observation confirmed that some patients lay on their bed completely immobile, for minutes or even hours, without sleeping. At day 0, six of the patients had immobility periods in the morning, but only one subject reported having slept. In the afternoon eleven patients had immobility periods, with seven reporting a short episode of sleep.

Group results

The hourly distribution of activity parameters is illustrated in Fig. 2. At day 0 the activity curve was characterised by several troughs (<70 movements/h), which occurred late in the morning, in the early afternoon, and around 1800 hrs. At the end of the hospital stay (day D), the activity remained high throughout the day. These changes in activity were paralleled by modifications in the number of immobility epochs. The number of minutes/hour without movement during the night decreased from day 0 to day D. At day 0, the main diurnal peak of immobility was observed around 1500 hrs, with a secondary peak before noon. These immobility peaks did not correspond to any restraint due to hospital schedule or treatment commitments; they tended to disappear in each patient as the clinical state improved. At day 8, the activity level was intermediate between those of day 0 and day D, with a trough of activity and a peak of immobility still found at 1500 hrs.

We analysed the changes of motor activity parameters in relation to clinical improvement. The number of immobility epochs significantly decreased from day 0 to day D: this change was more significant for the night (day 0, 11.4 ± 4.6 ;

FIG 1. A 17-day recording of motor activity of an endogenous depressive 40 year old female. (a) On the left, each line illustrates the distribution of motor activity levels recorded every 15 minutes over a 24-hour period. On the right, each bar indicates the mean activity level by 15 minute epochs and by 24 hours. Treatment and clinical state estimated by the HAMD score are also given. (b) The mean level of the same parameter for the entire duration of hospitalization. (c) On the left are the immobility epochs during 24 hours; on the right, the total number of immobility epochs in each 24 hour period.

day 8, 9.1 ± 3.7 ; day D, 7.2 ± 2.8 ; $F_{2,33} = 5$, $P < 0.02$) than for the combined day and night period (day 0, 23 ± 10.4 ; day 8, 19 ± 6.5 ; day D, 14.5 ± 6.4 ; $F_{2,33} = 3.8$, $P < 0.05$). Although the 24-hour mean level of activity increased, this increase was not significant (day 0, 47.6 ± 20.5 ; day 8, 61.9 ± 22.9 ; day D, 64.3 ± 13.4). Although the relationship between activity level and immobility was not a reciprocal one, we found a significantly negative correlation between them (day 0, -0.66 , $P < 0.05$; day 8, -0.50 , $P < 0.05$; day D, 0.55 , $P < 0.05$).

In general no significant correlation was obtained between the clinical scales and individual levels of immobility or activity at day 0 and day D. At day 8, significant correlations were found: a positive one between retardation scores and 24 h immobility levels ($\rho = 0.58$, $P < 0.05$), and a negative one between retardation scores and activity levels ($\rho = 0.61$, $P < 0.05$). When improvement at day D was expressed as a percentage of the initial value of a given scale, only one significant positive correlation was found between

the improvement of the self-ratings of depression given on visual analogue scales and the 24-hour immobility epochs ($\rho = 0.64$, $P < 0.05$).

Individual cases

The number of immobility epochs appeared to be more closely related to the clinical state than the activity level. Fig. 3 illustrates three individual cases.

Patient A exhibited a mean level of activity which transiently increased as a result of the treatment (clenbuterol), but without a clear change in her depressive state, while the immobility index remained high. The immobility index started to decrease only when the clinical state had improved.

Patient B did not present true retardation. In his case, as well as in two other patients who had a retardation score at the limit of normal (< 14) on admission, clinical

FIG 2. Hourly distribution of activity and immobility levels at the beginning of hospitalization (day 0) and at the end of hospitalization (day D).

improvement was reflected only by a decrease of immobility parameters, without changes in the activity levels

Two patients whose clinical improvement was insufficient to reach the criteria described above left hospital while still depressed. One of them (C) showed activity and immobility levels which had fluctuated from day to day without clearly increasing or decreasing trends.

The values of clinical scales obtained on the same days are given in Table I.

Discussion

The wrist activity monitor was readily accepted by the subjects, and is a good way to collect, in a relatively unobtrusive fashion, continuous longitudinal data for long periods in depressed patients. Wrist activity in unipolar depressed patients has rarely been monitored, and the results obtained previously with a similar device (Wehr *et al*, 1982) cannot be directly compared with the present data—mainly because of differences in characteristics of the respective patients. We found that motor activity in the depressed state was significantly lower than that found in the euthymic state in the same subjects; this is in agreement with several studies (Foster & Kupfer, 1975; Post *et al*, 1977; Wehr *et al*, 1980; Wolff *et al*, 1985). While a correlation between motor

activity and clinical state has been observed in 17 unipolar or bipolar depressed patients (Foster & Kupfer, 1975) as well as in one manic-depressive patient (Post *et al*, 1977), other authors (Kupfer *et al*, 1974) have failed to obtain a significant correlation. The latter authors reported that there were unimproved patients with high anxiety scores and high levels of activity, which could have been a possible cause of the lack of correlation. Absence of correlation between activity and self-report of mood is in agreement with the results of Godfrey & Knight (1984).

However, the results concerning the immobility index are more interesting; both for the entire 24 hours and for the night alone, they progressively decreased as the clinical state improved. This observation was surprising, since sleep disorders with nocturnal awakenings are frequent symptoms of depression. To our knowledge, this study underlines for the first time the importance of immobility as a function of the mood state, but the lack of correlation between immobility and HAMD score indicates that this immobility cannot be used as an absolute index of depression. However, in agreement with the significant correlation between individual feeling of improvement and improvement of immobility, this

FIG. 3. Evolution of the activity parameters in three patients. The black bars show the mean activity level in a 15 minute period, averaged over 24 hours. The shaded bars show the number of immobility epochs in each 24 hour period. Patient A was a 48 year-old female (non-endogenous depression); patient B was a 76 year-old male (doubtful endogenous depression, anxious-agitated); patient C was a 51 year-old female (non-endogenous depression, non-responder).

immobility index can be used as a measurement of the evolution of depressive illness in a given patient. It could also be used to judge the efficacy of the treatment. Immobility therefore seems to be a better index of depression than the activity level; while motor activity may be reduced in depression, the lack of initiation of spontaneous movements appears to be a more fundamental deficiency, and is similarly observed in non-retarded patients.

The activity troughs and immobility peaks occurring before noon and around 1500 hrs were partly

related to naps. The circadian fluctuations of activity parameters in our patients have been described elsewhere (Benoit *et al*, 1985). Kupfer *et al* (1972) have noted a strong correlation between a low level of activity at night and sleep. In the first few days after admission our subjects reported frequent naps around 1500 hrs, but not in the morning. The episodic occurrence of immobility over the 24-hour period suggests the release of an ultradian sleep-wake rhythm in depression. An ultradian rhythm of prolactin secretion (Mendlewicz, 1983) and body temperature (Nikitopoulou & Crammer, 1976) have been reported in depressed patients.

The great number and long duration of immobility episodes observed in our patients raise the question of whether pharmacological treatment, particularly by benzodiazepines, may have been a cause of the immobility. Borbely *et al* (1983, 1984) have shown that a single hypnotic dose of a benzodiazepine taken before bedtime enhances night-time immobility. While the precise role of hypnotics in the present study cannot be reliably assessed, there are some indications that they did not exert a major influence. Although medication with benzodiazepines in eight of the patients had begun prior to admission, the level of immobility was high for all patients on day 0. It was thus felt that the continuation of this treatment did not prevent the decrease of immobility in relation to the clinical improvement. Furthermore, in the two patients who did not respond the immobility index did not change, although all patients received similar drug treatment. Even though medication does not appear to have been the major factor in inducing immobility, the problem needs to be further investigated; it is possible that frequent episodes without movement constitute a specific feature of depressive illness. If this is confirmed in further studies, immobility could be a valuable index of depression.

Patients Who Break Their Fast Before ECT

G. E. BERRIOS and G. SAGE

Of 81 patients receiving ECT during a period of 24 months, 21 ate or drank something, against medical advice, shortly before ECT was due. Compared with controls, the fast-breakers were less often married; were more likely to be detained under a section of the Mental Health Act; had an unfavourable view of ECT; and had often not given consent for ECT. Fast-breaking was more likely to occur after four or more ECTs. Amongst the fast-breakers there was a significant correlation between age and (a) number of previous ECTs; (b) treatment at which the fast-break occurred. The more drugs the patient was taking the more likely it was that the fast would be broken early in the course of ECT.

Little is known of the clinical characteristics of patients who refuse ECT or those who, while not overtly refusing, avoid receiving it by breaking their fast. One may speculate that the latter group may be constituted of at least two sub-groups: patients who forget that they must not eat and patients who wilfully eat as a form of passive resistance. However, this distinction is based on the ascertainment of motives and so is difficult to make in clinical practice.

This paper reports on a prospective study into the more objective clinical characteristics of a cohort of fast-breakers.

Method

The study was carried out in a 30-bed acute unit (Friends Ward) in Fulbourn Hospital, Cambridge. All patients receiving ECT during the period of 24 months starting on 13 July 1983 were included. There were 617 admissions during the period in question: 76 patients received ECT, of whom 21 broke their fast at some time.

Fast-breaking was defined as eating or drinking, against clear medical advice, during the 8 hours prior to ECT. Due to a ruling by the consultant anaesthetist in charge, such fast-breaking led automatically to a cancellation of that particular treatment. In emergency cases the patient was kept fasting from the time of the incident and the treatment was postponed until the afternoon.

Information was collected by means of specially formatted data sheets which were completed immediately after the incident. These requested data on the patient's age, sex, civil status and legal status under the Mental Health Act; whether he gave consent to ECT, the treatment at which the fast was broken; the patient's and family's attitude to ECT; the patient's previous experience with ECT, medication, and ICD-9 diagnosis; the psychosocial state of the ward; the number of nurses working on the particular shift; and the number of empty beds (an indirect index of overcrowding).

The fast-breakers ($n=21$) constituted the index sample. There were 55 other patients who received ECT and these constituted the control sample. Five control subjects

received ECT twice during the period in question: in each case only the first course was included in our analysis.

In the first stage of our analysis the index sample was considered separately and the correlations between all its variables were examined. In the second stage the index and control samples were compared on those variables for which they were not matched. Statistical analysis was carried out by means of the Minitab Statistical Package (available in the Computer Laboratory of the University of Cambridge).

Results

There was a predominance of females amongst the fast-breakers (18 out of 21) but this reflected a bias in the hospital population. Significant correlations (Pearson correlation coefficient) were found in the index sample between age and (a) the number of previous ECTs ($r=0.43$; $P<0.02$); (b) the ECT at which the fast was broken ($r=-0.51$; $P<0.008$); and (c) the drug score ($r=-0.53$; $P<0.006$). There was a tendency for the fast to be broken after four or more ECTs, and the ECT at which the fast was broken was significantly correlated with the drug score ($r=-0.61$; $P<0.01$). No other correlations were found between any of the following variables: number of previous courses of ECT; the number of nurses on the ward; the number of empty beds; drug score; psychosocial climate of the ward.

The index and the control groups were not different in terms of age, sex, diagnosis, drug score, number of previous ECTs or family attitude towards ECT (Table I). There were however some statistically significant differences: the fast-breakers included more subjects who (a) were divorced, single or widowed; (b) were detained under a section of the Mental Health Act; (c) held an unfavourable view of ECT; and (d) had not given consent for ECT.

Discussion

The identification of potential fast-breakers is of some clinical importance. This form of behaviour interrupts treatment; it may prolong the hospital

TABLE I
Comparison of patients who broke their fast before ECT (index sample) with a control group

	Index sample (n = 21)	Controls (n = 55)	Statistic	Significance
Age (years): mean, s.d.	47.7; s.d. 19.7	46.9; s.d. 15.8	$t = 0.159$	NS
Sex	3 M/18 F	21 M/34 F	$\chi^2 = 2.98$	NS
Civil status: married/other	8/13	39/16	$\chi^2 = 5.61$	$P < 0.05$
Legal status: informal admission/MHA	11/10	45/10	$\chi^2 = 6.58$	$P < 0.01$
Consent for ECT	12 Yes/9 No	48 Yes/7 No	$\chi^2 = 6.59$	$P < 0.01$
Diagnosis (ICD9)				
Manic-depressive depressed (296.1)	14	39	$\chi^2 = 0.31$	NS
Manic-depressive, manic (296)	4	8

Schizoaffective (291.1)	1	2		
Attitude to ECT (favourable/neutral/unfavourable)				
Family	11/9/1	24/28/3	$\chi^2 = 0.46$	NS
Patient	7/6/8	12/35/8	$\chi^2 = 8.27$	$P < 0.01$
Drug score: mean, s.d.	2.52; s.d. 1.36	2.60; s.d. 1.57	$t = -0.209$	NS
Previous courses of ECT: mean, s.d.	0.85; s.d. 1.06	0.76; s.d. 0.94	$t = 0.35$	NS
Duration of admission (days): mean, s.d.	40.6; s.d. 25	35.8; s.d. 21	$t = 0.78$	NS

stay and so increase costs; and it may damage the relationship between the patient and the staff.

This paper has identified a cluster of features which may help the clinician to identify such patients. The fast-breaker can be male or female and of any age but is likely to be single, divorced or widowed rather than married; to be detained under a section of the Mental Health Act; not to have given consent to ECT (even if able to do so); and to hold unfavourable views on ECT. The fast tends to be broken after four or more ECTs. Confusion, memory impairment and the total amount of medication taken by the patient while receiving ECT do not seem to be important factors. Indeed, in our study only one patient claimed to have forgotten the instruction.

Tea- and coffee-drinking were the most common method of fast-breaking and the action tended to occur within the three hours prior to ECT. The subjects were very rarely willing to provide an account of their motives.

Our initial hypothesis was that environmental factors such as the psychosocial state of the ward, the number of nurses working on the particular shift, and the number of empty beds might be important. This was not borne out by our findings.

The fact that there were more fast-breakers than controls detained under a section of the MHA sug-

gests that the condition of the fast-breakers was more severe, or their behaviour more disordered. In fact there was a tendency for fast-breakers to stay in hospital longer than controls, but the difference did not reach statistical significance. There was no difference in outcome between the two groups, nor did the index sample receive more psychotropic medication than the controls. Since we did not include specific measures of severity, this issue remains unresolved.

We conclude that wilful fast-breaking was more common than forgetfulness or confusion in our sample. It is hypothesised that this represents some form of passive resistance which may be related to increased experience of side-effects as the course of ECT progresses, since fast-breaking tends to occur during the later stages of the course. The more drugs the patient was taking the earlier he tended to break his/her fast, which suggests that medication may amplify any unpleasant side-effects of ECT. Another hypothesis is that ECT produces increased arousal and psychomotor reactivation, leading to disinhibition and increased self-assertion.

It is recommended that patients meeting the criteria mentioned above are subject to special observation and given special counselling before and during any course of ECT.

Psychosocial Effects of Mastectomy: Is it Due to Mastectomy or to the Diagnosis of Malignancy?

T. T. ALAGARATNAM and N. Y. T. KUNG

Twenty-three consecutive married and sexually active Chinese women treated for breast cancer were compared with a randomly selected group of 34 female patients suffering from different kinds of malignancies. A structured interview was used to study both groups. The breast cancer group were found to be less depressed and more emotionally stable than those suffering from other malignancies, suggesting that the diagnosis of malignancy was the more important factor in the psychosocial morbidity of these patients.

Many clinical studies have shown that mastectomy for breast cancer is associated with considerable emotional trauma. These studies have usually centred around the immediate pre- and post-operative periods of their treatment, and there have been few long term follow-up studies (Morris *et al*, 1977, two years; Craig *et al*, 1974, five years) of patients surviving breast cancer. Furthermore, those studies were carried out on women living in a Western society with cultural backgrounds very different from those of Oriental women. The aims of the present study were to ascertain

- (a) the long-term psychosocial sequelae of mastectomy
- (b) whether these sequelae in Oriental women were any different from those observed in women living in Western society
- (c) whether the emotional morbidity of women undergoing mastectomy was any different from that of survivors of other cancers.

Method

Over a period of six months, 23 consecutive married Chinese females who were long term survivors of breast cancer were recruited for the study. They were compared with a control group of 34 Chinese female patients who were long-term survivors of other types of cancer: thyroid ($n=10$), stomach ($n=6$), colon and rectum ($n=13$), liver ($n=2$) and oesophagus ($n=3$). The breast cancer patients were all under the care of one surgeon; those in the control group were patients undergoing treatment in the same institution but under the care of different surgeons. Both groups were comparable as regards age, time since commencement of treatment, and the different modalities of treatment received (Table I). None of the patients in the control group had any major postoperative complications which could have prolonged their stay in hospital. Patients with rectal cancer were those who underwent sphincter-conserving resections of the rectum, they did not have open perineal

wounds or colostomies. Patients with breast cancer were those who had operable tumours ($T_{1,2}N_{0,1}M_0$); they underwent mastectomy and subsequently received adjuvant radiotherapy, chemotherapy, or both. None of these patients underwent any form of breast reconstruction. They all wore padded brassieres to conceal their deformity; none of the breast cancer patients had lymphoedema of the arm. Patients in both groups were fully aware of the natural outcome of their respective illnesses; no patient in either group had a past history of mental illness or had sought psychiatric treatment before the onset of their present illness. No formal preoperative psychiatric assessment was made in any of these patients.

A structured interview was used to compare the groups; and responses were graded as mild, moderate or severe. All patients were interviewed by a single assessor. Particular attention was direct to

- (a) assessment of depression by the Beck Depression Inventory (DI); cut-off score of 12 (which we have found from our experience with the local population to be valid) was used in the assessment of patients. Inquiries were also made regarding addiction to alcohol and excessive use of tranquilizers and sedatives
- (b) changes in sexual activity and any special sexual problems that patients experienced
- (c) changes in interpersonal relationships within the family and among friends and neighbours.

In addition, both groups were tested with the Eysenck Personality Inventory (EPI) for neuroticism. Chi-squared analysis was used to detect any significant differences in the data between the two groups.

Results

All women who were approached agreed to participate in the study, and co-operated fully in answering the detailed questions put to them. The majority of the patients studied were able to cope with the domestic tasks of housework, washing, cooking and shopping, and there were no significant differences in this respect between the two groups.

TABLE I
Clinical data of sample and control groups

	<i>Breast cancer (n = 23)</i>	<i>Other cancers (n = 34)</i>
Mean age: years	45.2 (s.d. 11.4)	41.8 (s.d. 9.7)
Mean time since start of treatment: years	6.9 (s.d. 1.8)	6.5 (s.d. 3.0)
Treatment received		
Surgery alone	5	15
Surgery and drugs	5	8
Surgery, radiotherapy and drugs	13	11

TABLE II
Depression and loss of femininity

	<i>Breast cancer</i>	<i>Other cancers</i>
Depression	11	21
Reasons for depression		
No reason	5	7
Financial matters	1	4
Diagnosis of malignancy	3	6
Changes in interpersonal relationships	2	4
Loss of femininity and changes in maternal role	5	6
Beck score	12.6 (s.d. 10.4)	20.8 (s.d. 8.9)

Depression was found in 47% of the breast cancer patients and 61% of the control group. On further questioning, well over half of these patients felt that fears arising from a diagnosis of malignancy, anxiety over financial matters and the loss of a close relationship were the causes of their depression. None of the breast cancer patients mentioned mastectomy as a cause of their depression. When specifically asked about feelings of loss of femininity or a sense of unworthiness in continuing the maternal role in the family, only 23% of the breast cancer and 17% of the control group reported such feeling. The breast cancer patients had a significantly lower DI score ($P < 0.01$) than those in the control group (Table II). In neither group was there any instance of increase alcohol consumption or addiction; nor were there any patients who were excessively dependent on tranquilizers and sedatives.

Only three (14%) of the breast cancer patients and nine (26%) of the control group felt that their husbands were less affectionate or were involved in extramarital affairs. Both groups experienced a decrease in frequency of sexual intercourse (moderate or marked decrease: breast cancer group 50%, controls 35%) and sexual satisfaction (moderate or

severe: breast cancer group 61%, controls 32%, $P < 0.05$) when compared with their pre-illness levels.

In the sphere of family and social life, there were many differences. Women in the control group experienced greater difficulty in adjusting to family life; there were greater parent-child tensions and more numerous instances of conflict with children (56%) than in the breast cancer group (34%). A similar finding was recorded in relationships with friends and social acquaintances; the control group (62%) found greater difficulty in social adjustment than women with breast cancer (14%). Furthermore, a greater number (56%) of women in the control group had suffered the loss of a close personal relationship over the past five years than those suffering from breast cancer (39%), but the difference was not statistically significant.

There was a significantly lower ($P < 0.01$) EPI neuroticism score in the breast cancer patients.

Discussion

The results show that even several years after the diagnosis and treatment of breast cancer, there still

remain a proportion of patients who never recover from the psychosocial morbidity of their illness. Of breast cancer patients, 47% were found to be depressed at the end of a mean period of seven years. This figure is much higher than that quoted in similar studies on Western women (Morris *et al*, 1977: 20% at two years; Craig *et al*, 1974: 20% at five years). It is unlikely that this high figure is due to the longer interval between completion of treatment and assessment in the present study; Morris *et al* (1977) showed that there is no great difference in the proportion of women remaining depressed at one year, and at two years following mastectomy.

A further point of interest lay in the reasons elicited for the depression. Loss of femininity and physical disfigurement did not appear to be the most important reasons for depression. Rather, fears arising from a diagnosis of malignancy, with its implications of incurability, recurrent disease and premature death, worries over family income, and fears regarding social acceptability appeared to be more important factors. This finding is reinforced by the fact that women in the control group (none of whom had undergone mastectomy) fared worse. It is unlikely that this difference in the two groups could be attributed to differences in the modes of treatment received. Lyon (1977) had observed that radiotherapy is an important factor in post-mastectomy depression, and one would have expected, considering the larger number of breast cancer patients receiving radiotherapy, to observe a greater degree of depression in these patients than in the control group. It would appear that the emotional trauma of mastectomy plays a secondary role in the aetiology of depression, and it is more than likely it has a similar role in the overall psychosocial morbidity of patients with breast cancer. Further evidence for this view comes from the studies of Sanger & Reznikoff (1981), who compared patients undergoing mastectomy with those having the more recent breast-conserving surgical procedures for breast cancer. No significant differences could be found in body anxiety, general psychological adjustment, and marital satisfaction between these groups.

Maguire *et al* (1978) and Morris *et al* (1977) showed that 18% of patients undergoing mastectomy experienced moderate or severe sexual difficulties three months after treatment; at two years following treatment this figure had increased to 32%. It was further observed (Morris *et al*, 1977) that patients who deteriorated within the first three months after surgery were unlikely ever to return to their preexisting levels of adjustment. The high figures recorded in the present study for sexual difficulties (as evidenced by a decrease in frequency of

sexual intercourse and sexual satisfaction) experienced by both groups of patients appeared to support this view. These difficulties had occurred despite the fact that the majority of women had received the understanding, care, and emotional support of their husband. Only 4% of breast cancer patients and 15% of the control group felt that their husbands were less affectionate than before their illness. Further study is necessary to ascertain the factors involved in the deterioration in sexual relationships with time. Deterioration in physical health was certainly not a factor, as the majority of women in both groups were able to cope with their daily household chores. It is more likely that the conservative attitudes of Asian women to sex, and their natural reluctance to talk openly on sexual matters, were more important factors in their sexual maladjustment. None of the women had ever sought help from marriage counsellors, psychotherapists or even their general practitioners. A noteworthy finding was that there was no significant difference between the groups in the number of women having sexual difficulties; which again would suggest that the emotional sequelae of mastectomy may not be the most important factor in the sexual morbidity of breast cancer patients.

The study by Morris *et al* (1977) has shown that post-mastectomy women may also have difficulties in making social adjustments. However, these difficulties lessened with time. It was surprising, therefore, to note in the present study that even after a mean period of seven years following treatment, there still remained women in both groups who had difficulty in making adjustments in family and social life. However, it was women in the control group who had experienced significantly greater difficulties in adjustment, with 56% of them admitting to have lost a close personal relationship over the preceding five years.

Perhaps the most important finding in the present study is that post-mastectomy patients were at no greater risk of developing psychosocial morbidity than patients with other malignancies. It may be argued that the long interval of time between treatment and assessment permitted the breast cancer patients to adjust themselves more easily than those with other malignancies; this may be especially relevant as mastectomy in Oriental women may not cause the same degree of emotional distress it does in Western women. The breast, in an Asian environment, does not have the same sexual symbolism it has in the West. However, it is unlikely that these are valid reasons for the differences seen in the two groups. Worden & Weisman (1977) have shown, in a similar study of Western women, that post-mastectomy women were no worse off than women

suffering from Hodgkin's disease, malignant melanoma and cancer of the colon. A more likely explanation is that the diagnosis of malignancy (which was common to both groups) was a powerful factor in the psychosocial morbidity of these patients and that this overshadowed the emotional trauma of mastectomy in patients with breast cancer. It would appear from the present study that women with malignancies other than breast cancer could also develop serious psychosocial problems, and in many respects the need for therapy could be greater in these women than in women with breast cancer.

Inter-generational Conflict and Psychiatric Symptoms

M. F. EL-ISLAM, S. I. ABU-DAGGA, T. H. MALASI and M. A. A. MOUSSA

Secondary school pupils and their parents were investigated using the scaled version of the General Health Questionnaire (GHQ-28) and by a questionnaire designed to study attitudes involved in inter-generational conflict in psychiatric patients. Parent-pupil and interparental conflict in answers to the attitude questionnaires were taken as measures of inter-generational and intra-generational conflicts respectively. The former significantly exceeded the latter. Parent-student conflict was higher when the students involved were females, Kuwaiti, or had less educated fathers. The tendency of the number of reported GHQ symptoms to be higher in members of families with higher inter-generational conflict did not reach statistical significance. There is an apparent discrepancy between this finding and the prominence of inter-generational conflict in clinical material.

Inter-generational conflict has been known since the days of Socrates (Ness, 1959), although Mead (1970) stated that 'the breakdown between generations is wholly new: it is planetary and universal'. Western literature on inter-generational differences or the 'generation gap' reports a spectrum of findings. These extend from inevitability (Davis, 1940) and dramatised descriptions of active warring conflicts or attempts of the young to exist in the present without any linkage to the past (Michael, 1965; Feuer, 1969) at one extreme to denial of the existence of a generation gap (Lerner & Weinstock, 1972; Lauer, 1973; Barclay & Sharp, 1982) at the other.

Reports on inter-generational conflict from the Arab world relate it to several factors: parental attempts to direct children in accordance with parents' aspirations rather than their own interests (Hamza, 1959); exposure to Western influences (Nagati, 1963); adoption of more progressive values by the young (Sultan *et al*, 1972); rigidity of parental control (Torky, 1974); or loosening of parental control (Hassan, 1977). The conflict centres mainly around patterns of relationships in the Arabian family, methods of marriage, and the emancipation of women (El-Islam, 1983). Clinical research in the Arabian Gulf area revealed that inter-generational conflict was involved in the presentations of 57% of cases of attempted suicide, 20% of neurotic and depressive illnesses, and 17% of schizophrenic illnesses (El-Islam, 1974, 1976, 1979; El-Islam *et al*, 1983). Alcohol consumption to the extent of dependence may be motivated by anti-parental and anti-cultural attitudes of some youths in Gulf countries where the Islamic code prohibits the use of alcohol (Demerdash *et al*, 1981).

The present study examines the relationships

between inter-generational conflict, psychiatric symptoms, and some demographic variables of members of two generations in Kuwait, where major socio-economic and cultural changes have taken place since the discovery of oil, e.g. expansion of urban areas and shrinkage of Bedouin (nomadic) life. It was hypothesised that conflict differs according to nationality, sex, and upbringing (urban versus Bedouin) and that age and educational differences between parents and students correlate positively with conflict. The association of inter-generational conflict with case presentation in clinical material led to the hypothesis that greater conflict is likely to be associated with more reported symptoms.

Method

A stratified sample of secondary school pupils was obtained. One district was randomly selected from each province, and the schools in each selected district stratified according to sex; two government schools (one for males and one for females) were randomly drawn from each district. Age was controlled by including only third-year pupils (11th standard) in secondary schools (age range 15–19). The number of pupils drawn from each school was in proportion to the population density in the school's province. Selection procedures were based on a full directory of schools and pupils, provided by the Department of School Social Services. To give unbiased estimates, every unit in the final stage of sampling had a chance of being drawn.

Eight schools (four for girls and four for boys) were selected. The proportions of Kuwaiti pupils were in the region of 40%–60% in each school; non-Kuwaiti pupils in government schools are Mediterranean Arabs whose fathers have been employed for long periods in Kuwait. Third-year rather than final (fourth-year) pupils were selected because the latter are likely to be anxious on

account of the decisive nature of the final year in relation to future university education and career prospects.

The age and nationality of pupils and their parents were recorded. The level of education of parents was determined according to the highest level reached at school, and an education score given: 0=illiterate; 1=standards 1-4, 2=standards 5-8; 3=standards 9-12; and 4=higher standards. Since the pupils were in standard 11, their education score was 3. The education gap is the difference in education scores between family members, being negative if the parent's score exceeded 3. The locality where pupils spent their first ten years of life was recorded as Kuwait city (urban), Kuwaiti Bedouin (nomadic) areas, or outside the country of Kuwait.

For this investigation, inter-generational conflict was defined as disagreements between pupils and their parents (Jacobsen *et al.*, 1975). The former often seem to reject traditional attitudes to patterns of family relationships, methods of marriage, and the emancipation of women; these three areas were chosen for study on the basis of their prominence in clinical material. Such disagreement carries the potential for strife, although it is not necessarily associated with overt clashes as an expression of the ideational conflict.

An attitude questionnaire was designed for this study, consisting of 36 statements about attitudes to family relationships, methods of marriage, and the emancipation of women. (Both Arabic and English versions of the questionnaire are available from Professor El-Islam on application). Statements were derived from accounts of young patients whose illness involved conflict in these areas, from their parents, and from volunteers (mostly healthy relatives of patients), who were asked to describe current attitudes of members of both generations in these areas. Sixteen statements centred around family relationships (area 1), twelve around methods of marriage (area 2), and eight around the emancipation of women (area 3). Half the statements in each area expressed the traditional attitude, while the other half conveyed the non-traditional attitude, their order was randomised. Within each area traditional and non-traditional scores derived equally from agreement and disagreement answers to the statements provided.

Pupils were only included if they had lived with both genetic parents since childhood. Linear one-to-one parent-child differences, rather than differences between a parents' group and a children's group, were sought. The questionnaire was administered directly to parents and pupils, unlike the studies of Al-Aasser (1978) and of Melikian (1981), who relied on members of the younger generation to obtain information about their parents' value-attitude system as perceived by the youths themselves. For every pupil and parent, a score for non-traditional (liberal) answers was obtained in each area (maximums of 16, 12 and eight in areas one, two and three respectively). Conflicts in answers to statements were counted, and scores obtained for father-pupil, mother-pupil and father-mother attitude conflict in the areas examined.

To detect the presence of psychiatric symptoms in pupils and their parents, we produced an Arabic form of Goldberg & Hillier's (1979) scaled version of the General Health Questionnaire (GHQ-28). It was found necessary to modify

the form and style of the English test before it could be applied to Arabs; for example, a less condensed layout of alternatives facilitated the choice of answers, and items which did not translate well had to be rephrased to convey the meaning in common Arabic methods of parlance. GHQ-28 has four seven-item scales: somatic symptoms, anxiety and insomnia, social dysfunction, and severe depression. The answer to each question was chosen from four alternatives, related to the present state of health. For example, when enquiring about a symptom 'S', alternatives from which a candidate chose an answer would be: A. I never experienced S; B. My experience of S is no more than usual; C. My experience of S is a little more than usual; D. My experience of S is definitely more than usual. The scoring method 0, 0, 1, 1 was used for the A, B, C, and D alternatives respectively; the range of possible scores therefore extended from 0 to 28.

Both questionnaires (Attitude and GHQ-28) were administered at the same time by school social workers, who received prior coaching in the method of administration and in explanation of instructions and statements in case they should be asked to clarify them by pupils or parents. For illiterate parents, the social worker had to read the instructions and statements, and mark the answers on the questionnaire sheets.

Non-parametric methods were used; Kruskal-Wallis one-way analysis of variance by rank was used to test whether more than two groups derived from the same population. This test is more useful than extension of the median test, because it utilises more of the observed data. Pairwise comparisons of medians were made using the Mann-Whitney test; since it considers the rank value of each observation this test is more useful in deciding on rejection of the null hypothesis than the 'median' test, which depends on the location of observations in relation to the combined median.

Results

Initially, 479 pupils were asked to participate—equivalent to 5% of all 11th standard students in government schools—but only 414 agreed to have their parents involved. They were studied during the period December 1982 to February 1983. Thirty-three pupils living in one-parent families (30 Kuwaiti and three non-Kuwaiti) were excluded; the missing parent was often the dead father. In the remaining 381 subjects the nationality distribution was similar among both sexes: 123 male and 100 female Kuwaitis, 88 male and 70 female non-Kuwaitis.

Pupils had significantly higher median liberal attitude scores than parents, the difference between parents was significant only in the area of emancipation of women (Table 1). Examination of the median number of differences (i.e. the degree of attitude conflict) between pupils and fathers, pupils and mothers, and between the parents themselves in responses to the attitude questionnaire revealed significant differences between father-mother attitude conflict and both father-pupil and mother-pupil attitude conflicts. Differences between father-pupil and mother-pupil attitude conflicts were not significant for either male or female pupils.

TABLE I
*Liberal attitudes questionnaire. median scores for 381 families**

<i>Attitude area</i>	<i>No. of questions</i>	<i>Fathers</i>	<i>Pupils</i>	<i>Mothers</i>
1 Family relationships	16	6.4	7.4	6.4
2. Marriage	12	6.7	7.8	6.8
3 Women's role	8	3.1	3.9	3.5
Total	36	16.4	19.4	16.8

* $P < 0.001$ for differences between fathers, mothers and pupils in all areas, between fathers and pupils in all areas, and between mothers and pupils in areas 1 and 2.
 $P < 0.005$ between mothers and pupils in area 3.

TABLE II
Liberal attitudes, attitude conflicts and GHQ median scores: differences between male and female pupils

	<i>Male (n = 211)</i>	<i>Female (n = 170)</i>	<i>P</i>
Liberal Attitudes			
Area 1	7.5	7.4	NS
Area 2	7.7	8.0	0.007
Area 3	3.2	4.7	<0.001
Total	18.5	20.2	<0.001
Attitude Conflict with father			
Area 1	4.0	4.4	NS
Area 2	3.4	4.9	<0.001
Area 3	2.9	3.3	<0.001
Total	10.5	12.8	<0.001
Attitude Conflict with mother			
Area 1	4.0	4.4	NS
Area 2	3.2	4.4	<0.001
Area 3	2.5	3.2	0.002
Total	10.5	12.2	<0.001
GHQ Total	6.0	8.4	<0.001

Pupils reported more symptoms on GHQ (median 7.2) than fathers (median 3.0) and mothers (median 3.5); the differences between these groups were statistically significant ($P < 0.001$). Pairwise differences between pupils and either parent were statistically significant ($P < 0.001$), but the difference between the parents was not.

Differences between male and female pupils

When male and female pupils were compared, significant differences were found in both Kuwaitis and non-Kuwaitis

TABLE III
Liberal attitudes: differences in scores between Kuwaiti and non-Kuwaiti families

	<i>Kuwaiti families (n = 223)</i>	<i>Non-Kuwaiti families (n = 158)</i>	<i>P</i>
Father	15.4	17.5	<0.001
Mother	15.7	18.2	<0.001
Pupil	18.9	20.0	<0.002

in their attitudes, in their parent-pupil attitude conflict, and in their responses to GHQ (Table II). Female pupils in general had significantly more liberal attitudes than males, and significantly more parent-pupil attitude conflict in areas two and three. GHQ-reported symptoms among female pupils significantly exceeded those in males.

Differences related to nationality and childhood upbringing

Non-Kuwaiti pupils of both sexes were significantly more liberal than their Kuwaiti counterparts (Table III). Only 19 pupils spent their childhood outside Kuwait; they were excluded from this analysis. Pupils brought up in Kuwait city (urban area) were compared with those brought up in Bedouin (nomadic) areas outside the city; they did not differ significantly from each other in their median liberal attitude scores.

Age and education gaps

The ages of pupils ranged from 15–19 years (mean = 16.3). Pupils with father-student age gaps of less than 30 years were compared with those with age gaps of 30 years or more. Younger parents, especially fathers, tended to have higher median scores on liberal attitudes, but their parent-pupil conflict was not significantly different from that of older parents.

Compared with the less educated fathers, those with equal

TABLE IV
Median GHQ scores for above-median and below-median scorers on attitude conflict

Group	n	Median GHQ scores		
		Fathers	Mothers	Pupils
Father-pupil attitude conflict				
Above median	198	3	4	8
Below median	183	3	3	7
Mother-pupil attitude conflict				
Above median	174	3	4	8
Below median	207	3	3	7
Father-mother attitude conflict				
Above median	200	4*	4**	7
Below median	181	2*	2**	7

* $P=0.003$

** $P=0.014$

or higher education (education gap ≤ 0) had significantly higher non-traditional scores and tended to have lower parent-pupil attitude conflict scores in their families. Mothers were all younger and, with the exception of three Kuwaitis, less educated than fathers. Mothers whose education was less than their children's were significantly less liberal and had significantly more conflict with their children.

Differences in GHQ in relation to attitude conflict

We compared the GHQ scores of pupils with attitude conflict scores above and below the median. Higher conflicts tended to be consistently associated with higher GHQ symptom scores in all family members; the increase in symptoms with increase in conflict was statistically significant only in parents in relation to their own attitude conflict (Table IV). On the other hand, GHQ scores for subjects with liberal scores on the attitude questionnaire above and below the median did not show any consistent trends. Pupils who failed their final examinations in May/June 1983 (73) were examined as a separate group; their scores on the various parameters, including GHQ, did not differ from those of the sample population as a whole.

Discussion

The finding of significant differences between parent-pupil and father-mother attitude conflicts confirms that the idea of parent-pupil conflict has some basis in fact. That female pupils have more liberal attitudes than males seems to be a reaction to their socio-culturally disadvantaged position (El-Islam, 1982), for which non-traditional attitudes seem to offer a remedy. Hence, the differences in liberal attitude scores between male and female pupils are most prominent in the area of emancipation of women.

Our estimate of parent-pupil conflict, which derived from differences in each parent-child unit, is quite revealing in contrast with studies that looked for differences between pooled attitudes of parents and of pupil cohorts, where pooling masked linear differences and no generation gap was found (e.g. Freeman, 1972). The findings of Thurnher *et al* (1974) that women are less likely than men to conflict with those adopting different values and attitudes cannot be exemplified by our finding that female pupils have more conflict with their parents than males in the studied attitudes. Same-sex parent-child conflict did not differ significantly from different-sex parent-child conflict; this finding contrasts with the conclusion of Aldous & Hill (1965) that more inter-generational continuity exists in same-sex family lineages, and with the contrary findings of Jacobsen *et al* (1975) that more differences are encountered between same-sex parents and their children.

Greater attitude conflicts exist in Kuwaiti families at both the inter-generational and parental intra-generational levels. The roles of coexisting indigenous and imported value orientations are important in this respect. Non-Kuwaiti Arabs in Kuwait come from more Westernised Arab countries; they bring to Kuwait not only their expertise, but also their attitudes and life styles which are at variance with local tradition (Melikian, 1981). Moreover, the wealth of Kuwaitis following the discovery of oil has made it possible for them not only to obtain Western commodities, but also to be exposed to European and American attitudes and values, through the mass media and tourism.

The failure to find significant differences in liberal

attitudes between pupils with urban or Bedouin upbringing may point to the greater importance of the common current social conditions and social institutions in shaping attitudes. However, inter-generational conflicts in attitudes were greater in families of pupils who had also been exposed to greater Westernisation during their Kuwait city upbringing, as compared with families of students with Bedouin (nomadic) childhood. The difference was significant only in mother-pupil conflict, possibly because of the poorer education of mothers.

The scope of liberal attitudes adopted by our pupils was generally similar to that described by Mehryar & Tashakkori (1978) in Iranian students who had a similar educational standard: they rebel against traditional parental authority, arranged marriage systems, and the restriction of the role of women to marriage and mothering. The challenge involves attitudes related to methods of marriage and to the emancipation of women more than those related to the area of family relationships. Conflict in the latter area accounted for a relatively small portion of the total, although it was probed by 16 of the 36 items in the attitude questionnaire. There may be a core of inter-generationally agreed family relationships that forms a 'point of strength' in the Gulf family (Melikian, 1981).

Since older parents are likely to be also less educated, disentanglement of the correlates of parental age and education may be difficult (Meidan, 1981). Barakat (1960) and Al-Eassa (1979), in their studies of other Gulf communities, pointed to the excess of non-traditional attitudes among the educated, but did not study the conflicts arising therefrom. Since Kuwaiti men are more likely to remarry at an older age than non-Kuwaiti men (El-Islam, 1982, 1983), they tend to have larger father-pupil age gaps. Non-Kuwaiti men whose children are admissible to the government schools which were studied are mostly professionals or technicians, i.e. they are relatively better educated than Kuwaiti fathers, and hence educationally closer to their children.

The tendency to have a greater number of GHQ symptoms in association with above-median attitude conflicts and the absence of such a relationship between GHQ symptoms and liberal attitudes suggest that it is conflict of attitudes, rather than the adoption of non-traditional attitudes as such, that is likely to be associated with symptoms. Inkeles & Smith (1974), rather than discovering adversity, found better psychological adjustment in association with modernisation of social attitudes. What is important for the development of clinical symptoms seems to be the perceived inadequacy of supportive relationships in the face of stress (Henderson, 1981).

Since the area of family relationships is the least conflicting in the families studied, family relationships may absorb the tension of disagreements in other areas (Lowy, 1983), e.g. methods of marriage and emancipation of women.

We did not assess the mental health of pupils and parents by psychiatric interviews. Therefore, it is not implied that the observed attitude conflict and reported GHQ symptoms are necessarily indications of poor mental health. Moreover, the similarity of attitude conflict and GHQ scores in pupils who failed and those who passed their final school year examinations does not support a case for inter-dependence of attitude conflict, GHQ symptoms, and scholastic achievement. Kim *et al* (1983), however, attributed both symptoms and poor school achievement, at least partly, to a decline in traditional attitudes among adolescent students.

How can the frequent encounter of inter-generational conflict in clinical psychiatric practice be reconciled with the much less noticeable and statistically insignificant association between inter-generational conflict and GHQ-reported symptoms in this community sample? Masterson (1967) found that feelings of anxiety and depression were as common in adolescents who have never had treatment for psychiatric disorder as in a sample of adolescent patients. In their investigation of the generation gap, Rutter *et al* (1976) found that a large proportion of the adolescents examined by questionnaire reported insomnia and feelings of depression, yet their psychiatric examination often failed to detect any psychiatric disorder. They differentiated the common adolescent experience of turmoil associated with parent-adolescent 'alienation' from psychiatric disorder that associates with parent-adolescent 'stresses'. Our adolescents' feelings of turmoil were detected by the GHQ, although probably they were neither spontaneously reported as complaints nor noticed by adult family members. Only in a minority of adolescents does inter-generational conflict make it difficult for the family to cope with adolescent problems using its intrinsic resources; in these cases the conflict is instrumental in provoking a search for psychiatric help.

The clinical psychiatric significance of inter-generational conflict is therefore likely to be over-estimated if we rely solely on data from our clinical material. Moreover, since inter-parental conflict is significantly more likely to associate with GHQ symptoms in either parent than is inter-generational conflict with symptoms in pupils or parents (Table IV) no specific pathogenic effects could be attributed to the conflict being inter-generational rather than intra-generational. Finally, though conflict or

alienation may lead to psychiatric disorder, the reverse may also be true (Rutter *et al.*, 1976).

Since our study attempted to find group differences in the reported prevalence of symptoms, we used GHQ-28 solely for this purpose without attempting to demarcate illness and well-being, or to define 'cases' with cut-off points for sensitivity or specificity at this stage. The groups we studied cannot claim to be representative of the total youth population they derive from: obvious constraints include the requisites for admission of non-Kuwaitis to the government schools studied and the inability to investigate the paternal social class correlates of our findings. In Kuwait, social classes defined by standards of living are not consistently dependent on educational and occupational achievements (Kurtz, 1981).

Thus, our hypothesis that the magnitude of inter-

generational conflict varies with differences in nationality and sex was confirmed, but the hypothesis about relationship of conflict to locality of childhood upbringing was only partly confirmed. Inter-generational educational differences, rather than age differences as such, showed a positive association with inter-generational conflict. Our hypothesis that greater inter-generational conflict associates with more symptoms did not receive statistical confirmation.

Psychosocial Risk Factors and Urban/Rural Differences in the Prevalence of Major Depression

B. A. CROWELL JR, L. K. GEORGE, D. BLAZER and R. LANDERMAN

The Piedmont Health Survey interviewed 3798 adult community residents in a region of North Carolina. Current major depression was nearly three times more common in the urban than in the rural counties; rural residence decreased the risk of major depression for some, but not all, demographic subgroups. The risk of major depression was decreased for young rural residents, compared with their urban age peers; rural residence was more protective for young women than for young men. Rural residence appears to be a buffer against major depression.

Despite growing emphasis on the genetic and biological components of psychiatric disorders, the social origins of mental illness continue to receive attention. Urban or rural residence is one social characteristic that has a long history of consideration as a risk factor for psychiatric morbidity (Schwab *et al*, 1974; Neff, 1983; Dohrenwend & Dohrenwend, 1974); the usual hypothesis is that urban living places individuals at greater risk for psychiatric disorder—especially the more reactive or stress-induced disorders such as depression or anxiety. This is compatible with public images of urban and rural environments, and is based on the assumption that urban areas are characterised by change, interpersonal estrangement, anonymity, and conflicting values, whereas rural areas are characterised by social stability and integration, supportive interpersonal networks, and consensus about moral and political issues. Rural areas are also aesthetically superior to large cities—a skyline of high-rises and smokestacks cannot compare to the pastoral beauty of a pond surrounded by open fields or sheltering forests. Indeed, although results have not been unanimous, the majority of previous studies support the hypothesis of increased prevalence of psychiatric disorder in urban areas (Dohrenwend & Dohrenwend, 1974).

However, there are several reasons for continued exploration of this issue. Firstly, most previous studies of urban/rural differences in the prevalence of psychiatric illness used global scales of psychological well-being or numbers of psychiatric symptoms, rather than specific psychiatric disorders defined by reliable diagnostic standards. Secondly, urban/rural comparisons have often been made across rather than within studies, thereby obscuring urban/rural differences with regional, cultural, or methodological variations between studies. Thirdly,

most previous studies failed to take into account compositional differences between urban and rural areas: if urban/rural residence is a risk factor for psychiatric morbidity, that relationship should be observed once compositional differences (e.g. age, sex, socio-economic status) between urban and rural settings are statistically controlled.

However, there are other reasons to suspect the usual hypothesis that rural residents are advantaged in terms of the risk of psychiatric disorder—or at least to question its generalisability across time and space. Several authors (e.g. Flax *et al*, 1979; Srole, 1978) contend that the images of cities as evil and rural areas as peaceful enclaves have long been based more on romantic ideals than on realistic assessments of the two environments. Urban areas have been defended by those who point out that although cities may not be characterised by integration and cohesion, neighbourhoods within them are frequently stable and supportive, and may be the more appropriate unit of analysis (Srole, 1978). Others have pointed out that rural residents are more conservative and less flexible than their urban counterparts (Rogers & Burdge 1972; Hassinger, 1976), and that rural areas are not without social problems—isolation, lack of social and medical resources, outwards migration of the young, and relatively high rates of poverty and unemployment (Flax *et al*, 1979; Srole, 1978).

The potential effects of social change also may be relevant. Areas characterised by low population density may be considerably less 'rural' than they were 10–30 years ago. Mass communications (especially television), motorways, inwards migration of people who commute to urban jobs, etc., may have resulted in a significant degree of urbanisation of areas that remain sparsely populated. Thus, even if there has been an historical pattern of urban/

rural differences in the distribution of psychiatric disorder, that pattern may have been eliminated or substantially reduced by the homogenisation of society.

This paper examines urban/rural differences in the prevalence of current major depression. Previously (Blazer *et al*, 1985) we reported urban/rural differences in the prevalence of eight of the most common psychiatric disorders. Bivariate analyses suggested that the psychiatric diagnosis most strongly related to urban/rural residence was depressive disorder; current major depressive disorder was nearly three times more common among urban than among rural residents. Moreover, this difference persisted when the effects of standard demographic variables (i.e. age, sex, race, marital status, and five-year residential mobility) were statistically controlled (Blazer *et al*, 1985). The present paper builds on our previous work in two ways. Firstly, the degree to which the urban/rural difference in the prevalence of major depression is consistent across demographic sub-groups is analysed: the results suggest that rural residence significantly buffers the risk of major depression only among certain demographic sub-groups. Secondly, a multivariate logistic regression procedure is used to predict major depression on the basis of an expanded set of demographic variables and selected social characteristics which previous research suggests are risk factors for major depression. The multivariate analysis is important because it permits us to determine whether place of residence remains a significant predictor of major depression, after controlling for a variety of other demographic and social risk factors.

Compared with previous studies, these analyses have a number of distinct advantages: the dependent variable is a specific psychiatric disorder, rather than a global measure of symptom level or amount of impairment; the urban and rural subsamples are from the same geographical region and share a common history, cultural traditions, and political structure; and use of multivariate statistical procedures permits us to determine whether place of residence affects the risk of current major depression after normalising for urban/rural differences in the social demographic compositions of the two sub-groups.

Method

Sample and Data

The Epidemiologic Catchment Area (ECA) Program is a collaborative research project, funded by the National Institute of Mental Health. Its major goals are to examine

the prevalence of psychiatric disorders, risk factors associated with the onset of mental illness, and health service utilisation for psychiatric morbidity (Regier *et al*, 1984). Five universities participated, surveying defined local populations: Yale University (Greater New Haven, Connecticut), Johns Hopkins University (East Baltimore, Maryland), Washington University (Greater St. Louis, Missouri), Duke University (the Piedmont region of North Carolina), and the University of California at Los Angeles (East Los Angeles/Venice, California). The data reported here are from the Duke University ECA Project, locally called the Piedmont Health Survey (PHS).

Each ECA site randomly sampled its defined population to generate stratified random samples of approximately 3000 community residents and 500 institutional residents. Three sites, including the PHS, also obtained oversamples of older non-institutionalised adults. The sampling frame for the community sample and elderly oversample for the PHS consisted of a five-county area, encompassing two Community Mental Health Center catchment areas: Durham County, an urban county (based on size of residence codes used by the US Bureau of the Census); and Franklin, Granville, Vance, and Warren Counties, which are rural. The two catchment areas are approximately equal in total population, although the rural one is much larger in area. The findings in this paper are based on reports from community residents (including the elderly oversample); the institutional sample of the PHS will not be described.

Within the sampling frame, three-stage probability sampling was used to select respondents. In the first stage, small geographical segments were selected randomly, after being stratified to reflect the racial, socio-economic, and urban/rural compositions of the five counties; in the second, housing units within segments were randomly selected; in the third, once a selected household was rostered for usual residents, the Kish (1965) method was used to identify the designated household respondent. Households for community sample and elderly oversample were drawn from the same segments. The only difference in selection of respondents for these two subsamples was age: household members aged 18 and over were eligible for the community sample, while household members aged 60 and over were eligible for the elderly oversample. For the community sample, 3911 households were screened to generate a sample of 3015 respondents. In the elderly oversample, 3371 households were screened, generating a sample of 906 respondents. The combined response rate for the community and elderly samples was 79%. Reasons for non-response included inability to obtain a roster of household members (10%) and refusal of a designated respondent to participate in the interview (11%).

The analyses reported in this paper are based on a sample of 3798 respondents. Reasons that certain interviews were not used included physical or mental impairment too severe to permit a reliable interview ($n=80$), failure to complete the interview ($n=37$), and determination by the research team that the interview data were unreliable ($n=6$).

Respondents completed an interview lasting approximately two hours. Information about psychiatric disorders

was obtained using the Diagnostic Interview Schedule (DIS)—a highly structured interview designed to be administered by lay interviewers and capable of generating computer-based diagnoses for selected DSM-III disorders (Robins *et al*, 1981). The DIS elicits the elements necessary for a diagnosis: symptoms; their severity, frequency, and distribution over time; and whether they can be attributed to physical illness, alcohol or drug use, or are psychogenic in origin. Both the questions and the probes are fully specified, and the interview is pre-coded so that data can be computer-entered after editing. The DIS generates information about both current and lifetime prevalence of selected DSM-III disorders.

This paper focuses on one DIS/DSM-III diagnosis—major depression. A respondent was diagnosed as having major depression if he or she experienced symptoms sufficient to meet criteria for a major depressive episode and had no history of manic episodes. Other DSM-III exclusion criteria (American Psychiatric Association, 1980) were not used, largely because of recent data questioning their validity (Boyd *et al*, 1984). This paper reports only current major depression, defined as depression experienced during the six months prior to the interview. For the sample in this paper the prevalence of current major depression was 1.9% (based on weighted data), which is slightly lower than those reported by three other ECA sites (Myers *et al*, 1984).

Other variables included in analysis were respondents' demographic characteristics and selected social characteristics that previous literature suggest are risk factors for major depression. The demographic factors examined were age, race (essentially white or black in this sample), sex, education, place of residence (urban or rural), socioeconomic status measured in quartiles, and marital status. The other social characteristics examined have been closely linked to depression or to depressive symptomatology in previous research: the experience of one or more stressful life events in the past year (Markush & Favero, 1974; Brown & Harris, 1978), whether or not the respondent is the mother of pre-school children (Brown & Harris, 1978; Weissman & Paykel, 1974) and the degree to which a confidant is available, which appears to be an especially important dimension of social support (Lowenthal & Haven, 1968).

Methods of analysis

As reported previously (Blazer *et al*, 1985), current major depression was nearly three times more common among urban than among rural Piedmont residents. In order to obtain more detailed information about urban/rural differences in the prevalence of major depression, chi-squared tests were used to compare urban and rural residents within subgroups stratified on the basis of age, sex, and race.

In later analyses, logistic regression was used to examine the effects of urban/rural residence on major depression, controlling for demographic and social characteristics that previous literature and our earlier findings indicated are risk factors for major depression. Logistic regression is the best technique when the dependent variable is dichot-

omous, as is the case in predicting absence or presence of current major depression. Using logistic regression, independent variables may be either discrete or continuous; in this paper, all independent variables were coded in discrete categories. For each independent variable a set of two or more dichotomous dummy variables was created, $n-1$ variables were estimated in the logistic regression equation, where n is the number of dummy variables used to represent the total set of categories comprising the independent variable. Logistic regression analysis generates a coefficient for each variable in the equation; these coefficients equal the natural logarithms of the odds ratios for those predictors. The coefficients are presented here as odd ratios. Each omitted or reference category of the independent variable was assigned an odds ratio of 1.00; the odds ratios for the estimated categories represent the odds having major depression relative to the reference category. Similarly, tests of statistical significance were based on a comparison of the estimated categories with their reference categories (Kleinbaum *et al*, 1982).

Most of the analyses reported here, and all tests of statistical significance, were based on weighted data. The design weights used correct for non-response, adjust for household probability selection, and generate distributions that match the age, sex, and race profiles of the adult population of the five county area generated by the 1980 US Census. Although the distributions remain adjusted for these factors, sample size was downweighted to the original number of respondents for tests of statistical significance.

Results

Table I shows the demographic and social characteristics of the PHS respondents, based on both unweighted and weighted data; distributions are presented separately for urban and rural residents. The unweighted distributions are greatly skewed by the large proportion of older respondents; e.g. in addition to affecting the age distribution, inclusion of the elderly oversample in the unweighted data also inflates the proportions of the sample who are female, white, widowed, and have low levels of education and socio-economic status. The weighted distributions, however, are corrected for the elderly oversample and other biases, resulting in demographic distributions that are representative of the adult population of the five counties.

As indicated by the weighted distributions, the PHS sample has age and sex distributions characteristic of both North Carolina and the USA generally. The sample has a large proportion of non-whites, the vast majority of whom are black; the rural counties have higher proportions of non-whites than the urban county. The distributions for educational attainment and socio-economic status (SES) are somewhat lower than comparable national figures—especially for the rural PHS respondents. This reflects the generally lower educational and occupational attainments of Southerners in general and of rural Southerners in particular. In terms of the social risk factors, about one-third of the sample had experienced one or more stressful life events in the past year, about 10% of the sample consisted of women with small children at home, and three-quarters

of the respondents reported that they usually had a confidant available. Interestingly, the social characteristics—unlike the demographic variables—did not differ between urban and rural residents.

Table II shows the prevalence of six-month major depression by urban/rural residence, stratified for age, sex, and race. The significance tests refer to the difference between urban and rural prevalences within the demographic subgroups. The data strongly suggest that rural residence buffers young adults, rather than middle-aged and older adults, from major depression. Moreover, although this pattern holds true for both sexes, the urban/rural difference is more striking and consistent for young women. In contrast, the relationship between place of residence and the prevalence of current major depression does not appear to differ by race.

The distribution of prevalences in Table II strongly suggests an interaction between age and urban/rural residence affecting the prevalence of major depression—and perhaps a three-way interaction involving age, sex, and place of residence. Unfortunately, the small number of cases of current major depression in the PHS sample precludes stable estimates of these and other potential interaction effects in both the cross-tabular and logistic regression analyses.

Table III gives the results of the logistic regression analysis in which demographic variables and selected social characteristics are used to predict major depression. Six of the nine independent variables exhibit significant odds ratios. Most importantly, from the perspective of this paper, place of residence remains a significant predictor of major depression, normalising for other demographic and social factors. As was true in the bivariate case, the odds of having major depression are nearly three times greater among urban than among rural residents. As expected on the basis of previous literature, the likelihood of having major depression also is significantly related to sex, SES, being a mother with small children, experiencing recent stressful life events, and the availability of a confidant. In contrast, normalising for other variables in the equation, marital status, race, and age were not significantly related to current major depression.

The six statistically significant predictors of current major depression differ in magnitude. Absence of a confidant is an especially strong predictor of depression (odds ratio = 3.79). Stressful life events and sex are also relatively powerful predictors, as would be expected on the basis of previous research (odds ratios of 2.31 and 2.93, respectively). Only one of the levels of SES is significantly different to the reference category; nonetheless, two of the estimated coefficients exceed 2.0, and we conclude that SES is an important predictor of major depression. More troubling than the size of the coefficients for SES is their direction. Normalising for other variables in the equation, SES exhibits a non-linear relationship with major depression. Moreover, all three higher levels of SES increase the odds of having major depression, compared with the lowest category, and upper middle class respondents are at greater risk. These findings are contrary to the more usual pattern of increased symptomatology among lower SES persons (Dohrenwend & Dohrenwend, 1969),

and may reflect the fact that in this study other demographic correlates of SES have been statistically controlled. Finally, as expected, mothers with pre-school children at home are at greater risk of current major depression than other respondents. This odds ratio is somewhat smaller than the others, but is significant.

The logistic regression for which results are given in Table III is our choice of a 'final model'. A series of logistic regression equations were estimated, the models differing slightly in the specific combinations of independent variables included. This equation was chosen as the most useful model, i.e. it includes those variables that proved to be most relevant in terms of their predictive power or importance as control variables. Education was not included in

the final model, because its direct effect was non-significant and because its inclusion was partially redundant, given that the SES scores are based on a weighted combination of education, occupational status, and income. Employment status was included in some earlier models, but its predictive power and effect as a control variable were negligible—again, perhaps, because of the inclusion of SES. Death of a parent during childhood (a variable suggested as a risk factor for depression in previous research), residential relocation during the past five years, and household size were also tested, but eliminated because they served no purpose in terms of predictive power or control variables.

The results in Table II suggest an interaction between age and place of residence in the prevalence of current major depression. Although the low overall prevalence of major depression precluded testing this possible interaction, separate logistic equations were estimated for relevant subgroups to explore this possibility further. In all of these subgroup analyses, the ratio of independent variables to number of cases in the dependent variable was unfavourable. Consequently, the results of these analyses must be interpreted cautiously; although they have not been tabulated, the findings will be briefly described.

Firstly, the equation in Table III (with the exception of place of residence) was estimated separately for urban and rural residents. As expected, age had substantially different effects in these two models. In the equation for urban residents, younger respondents were at the greatest risk of major depression, normalising for other variables. The opposite was true in the equation for rural residents: younger respondents were at the lowest risk of major depression. Secondly, the logistical equation in Table III (minus age) was estimated separately for respondents aged 18–44 and for those aged 45 and older. Again, the findings support the pattern of subgroup differences in Table II. Place of residence was a significant predictor of major depression for younger respondents (with urban residence increasing the risk of depression), but was not significant for older respondents.

Discussion

Two findings are of particular importance to our understanding of the role of urban or rural residence as a risk factor for current major depression. Firstly, the results suggest that rural residence is a more important buffer against major depression for some demographic subgroups than for others. Rural residence significantly decreases the risk of major depressive disorder only among young adults aged 44 and younger and is perhaps more of a buffer for young women than for young men; this finding is useful because it suggests that the protective qualities of rural life are not uniformly experienced by all rural residents. Secondly, the logistic regression analysis strongly suggests that place of residence is a significant predictor of major depressive illness, normalising for a variety of demographic and social

characteristics which have been suggested as risk factors for depression in previous research. This finding suggests that the advantage enjoyed by rural residents in terms of risk of depression is not due to compositional differences between urban and rural populations. This is especially relevant in that the demographic profiles indicated substantial demographic differences between the urban and rural subsamples.

Given these findings, it remains unclear why or how rural residence translates into a protective buffer against the risk of current major depression. Our expectation was that the bivariate relationship between place of residence and major depression would be eliminated, or at least substantially reduced, after demographic differences between the urban and rural subsamples were taken into account. At this point, we can only echo the sentiments of earlier studies which suggest that there is some elusive quality about rural environments that serves as a protector against psychiatric illness—in this case, major depression. Although we have not identified that quality yet, we have at least ruled out a number of potential contenders. Moreover, it appears that, at least for depressive disorder, the quality we are seeking must be one which has a stronger effect on young adults than on middle-aged and older persons.

The age-specificity of the relationship between place of residence and major depression complicates interpretation and the search for explanatory factors. It argues against the perspective that the uniqueness of rural living is being undermined by urbanisation and social change. Numerous investigators have demonstrated consistently that social trends have greater effects on younger members of the group experiencing change (Ryder, 1965; Riley, 1976). Thus, if rural environments are becoming more urban-like in terms of lifestyles and values, we would have expected the exact opposite of what we observed, i.e. that urban/rural differences would be greater among older adults. It is possible that social change in general is experienced first and most rapidly in urban areas and that, because young adults are most affected, the impact of social change is to elevate the prevalence of major depression in young urban residents compared with their rural age-peers. There are no empirical data supporting this hypothesis, however.

This study has several limitations. Firstly, like all self-report surveys, the DIS and other instruments included in the PHS are vulnerable to deliberate or inadvertent misreporting of information. This is especially pertinent to the DIS, where accurate reporting of sometimes sensitive and highly personal

symptoms is required for valid measures of psychiatric disorder. The effects of forgetting symptoms, however, should be minimised in this study because of the exclusive focus on current disorder. Moreover, there is no reason to believe that the reporting of symptoms would be unequally distributed across urban and rural residents.

Secondly, although the DIS is designed to elicit diagnoses compatible with DSM-III diagnostic criteria, the diagnoses generated by the DIS are not identical to those made by psychiatrists performing diagnostic assessments of clinic patients (Robins *et al*, 1981; Helzer *et al*, 1985). Nonetheless, the DIS generates reliable diagnoses, and appears to be superior to the instruments used in most previous studies of urban/rural differences in psychiatric disorder. Again, there is no reason to suspect that the validity of the DIS would be different for urban and rural residents.

A final limitation of the study is potentially more consequential. This issue is related to two characteristics of the data used in this study: the data are cross-sectional, and retrospective data about migration history were not collected. The issue of concern is selective migration, which has been a long-term concern in studies of urban/rural differences in the prevalence of psychiatric illness. Given our reliance upon cross-sectional data and the lack of a detailed migration history, we cannot know whether current residence as urban or rural preceded or followed the onset of depressive disorder. We believe that this is less of an issue because of our focus on current disorder—i.e. the more recent the disorder examined, the less likely that the respondent has subsequently moved. Moreover, although the PHS did not obtain a migration history, information was elicited about length of residence at the respondent's current address; this factor was not significantly related to major depression and was not useful as a control variable. Length of residence does not directly cover the issue of selective migration, in that we could not distinguish between moves between and within urban and rural settings. Additionally, the most recent move may not be the crucial piece of information; for example, Schwab *et al* (1974) found a significant relationship between

size of community of origin and psychiatric impairment as measured by the Health Opinion Survey, regardless of current residence. Thus, we cannot rule out selective migration or community of origin as possible explanations for the observed urban/rural differences in the prevalence of current major depression.

Because these findings raise a number of questions, they point to exciting areas for future research. The trend toward examining the epidemiology of specific psychiatric disorders (rather than symptom scales) should be continued. The PHS research team is currently examining urban/rural differences in the prevalences of anxiety disorders and alcohol abuse and dependence; although only preliminary analyses are available, it appears that rural residence does not invariably decrease the risk of psychiatric disorder. As other psychiatric disorders are examined, care should be taken to determine whether the effects of place of residence are invariant across demographic subgroups and remain statistically significant after normalising compositional differences between urban and rural residents. Such information refines our understanding of the effects of place of residence, and has the potential to identify some of the mechanisms underlying bivariate relationships between urban/rural residence and psychiatric disorder. Perhaps most importantly, effort should be devoted to specifying what it is about urban and rural environments that affects the risk of psychiatric disorder. As operationally defined, the distinction between urban and rural residence is based simply upon population density; although it is possible that the number of people per square mile has a direct effect on mental health, it is more likely that place of residence now serves as a proxy for one or more important social processes that affect the risk of psychiatric disorder. Identification of those processes could have important implications for our understanding of the aetiology of psychiatric disorder and for its treatment.

Neurological Factors in Obsessive Compulsive Disorder Two Case Reports and a Review of the Literature

P. A. KETTL and I. M. MARKS

Two patients are described in whom an obsessive-compulsive disorder began just after the onset of epilepsy. Neurological factors in OCD are then reviewed, and clinical reports of patients with OCD and co-existing brain pathology, EEG abnormalities, CT scan changes and electrical stimulation of the brain discussed. It is concluded that neurological factors are present in only a minority of cases of OCD. Successful behavioural treatment is independent of such factors.

Obsessive-compulsive disorder (OCD) has long been an enigma in psychiatry because of its bizarre presentation. We report two cases in which typical OCD developed in teenage patients shortly after the onset of epilepsy. One patient had temporal lobe fits, the other grand mal fits. Both patients were free of obsessive-compulsive symptoms before the onset of epilepsy.

Case Histories

Case 1

A 16 year-old student had been well until the age of 11, when he developed left-sided classical migraine headaches. During a migraine attack at the age of 12 he had a fit, and subsequent investigation after more fits revealed a temporal lobe seizure disorder. Six months after the first fit the patient developed obsessive-compulsive symptoms. He felt an irresistible urge to clean things with the sleeve of his shirt, and soon wore holes in his jacket. He also started smoothing the velvet fittings at home so that the pile ran all in one direction. He later developed other compulsions, such as putting his handkerchief in his pocket in a certain way, or hanging up his trousers in an exact fashion with precise rituals which would take ten minutes or more to perform. The number three took on a magical significance, and the patient felt compelled to perform many acts three times; for example, he would dry his face three times after washing, or would cough three times when he had to cough. These tasks would have to be done in an exact manner, otherwise he would become consumed with worry. He feared that imperfection in these tasks would magically cause him to have a seizure, or to lose sleep at night.

There was no psychiatric illness in his family. One sister had suffered a febrile convulsion as an infant. The patient was raised by both parents at home, and had a warm relationship with them. They worked full time: the father was a policeman, the mother a secretary. He had one sibling, a sister one year younger. The patient was the

product of full term, normal delivery, and achieved normal developmental milestones. Early childhood was happy, and he had many friends and enjoyed sport. He began school at the age of five, and performance was normal until the onset of his obsessive-compulsive symptoms, after which his academic performance dropped.

The patient had migraine and temporal lobe epilepsy. Fits would occur with varying frequency, from two/day to one/week, and were treated with carbamazepine and phenytoin. An electroencephalogram (EEG) showed frequent isolated spikes and slow complexes of temporal lobe origin, more in evidence on the right side. A physical examination gave normal results.

On examination the patient had normal mood, with no thought disorder, hallucinations or delusions. Attention and concentration were relatively poor, because of interruption by his obsessions. His intelligence was slightly above average.

The patient had 3 months of in-patient treatment by exposure *in vivo* for his fears and self-imposed response prevention. His rituals improved by 50%, and he returned home to live with his family.

Case 2

A 21 year-old white male had a long history of mental subnormality and behavioral problems, following a head injury at the age of three. He had his first fit (grand mal) at the age of 15, and shortly after developed fears that he would be contaminated by dirt and began ritual handwashing to combat this. He became fastidious about the way he arranged his clothes or food, and would only sit down after performing a series of precise rituals. If these rituals were interrupted, or if his family did not co-operate with them, he would strike out at objects around him or at himself. Over the year before admission his rituals had increased, becoming more handicapping. He ritualised before almost every action, most of his day being taken up by the rituals. It took him an hour to drink a cup of tea, and two hours to eat a sandwich or to go to the toilet.

As an infant his birth, delivery, and development milestones had been normal. He had burns to both legs at the

age of one, and regressed temporarily. At the age of three he hit his teeth and head on a car, and all his teeth were removed under general anaesthesia. After this he was never again a normal child. He regressed permanently in development, and became a frequent behaviour problem. His behavioural outbursts and his mental subnormality resulted in his transfer to a school for the educationally subnormal. He attended a series of schools, but his outbursts made formal education difficult. After the onset of his epilepsy and rituals his education was further impaired.

Treatment with primidone and carbamazepine reduced the fit frequency from one per week to once every three weeks. His EEG showed spike and wave components, predominantly in the left anterior quadrant, against a background of a slow alpha rhythm. A computerised tomography (CT) scan showed an increase in ventricular size. He had out-patient psychotherapy between the ages of 7 and 12 for his behavioural symptoms, and was admitted in 1980 and 1981 in unsuccessful attempts to ameliorate his OCD.

On examination, he frequently ritualised. He spoke in a halting, staccato tone with short bursts of words, without thought disorder. His mood was normal, and he denied experiencing hallucinations or delusions. He was alert and oriented, but his memory was only fair: he could recall only two or three nouns after three minutes. His concentration was good, and he could perform the 'serial sevens' mental arithmetic test without error. His sight into his condition and judgement about social situations were limited, and his intelligence was subnormal (Wechsler Adult Intelligence Scale full scale IQ 65; verbal 72; performance 60).

He had in-patient behavioural treatment by exposure and response prevention and a token economy system. After more than 300 hours of treatment, few gains had been made.

Discussion

Modern ideas about OCD emerged in the 19th century. Charcot & Magnan coined the term 'onomatomania' for patients who were disabled by 'imperative ideas', and in 1890 Culerre noted a link between epilepsy and Charcot & Magnan's onomatomania (Tuke, 1894). Although Freud (1894) regarded obsessive states and neuroses, attributing their origin to repressed memories of sexual guilt, other writers continued to regard them as organic in origin. Tuke (1894) considered that they were the result of abnormal cortical function, a view supported by other authors in the early part of this century (Wexberg, 1938; Schilder, 1938).

Since these early reports a number of authors have detected 'organic' features in OCD, but there is marked disagreement about their frequency. Since the mind is the brain in action, psychopathology must at some level reflect dysfunction of brain activity. Our division of 'organic' from 'functional'

reflects our ignorance, as the two are at the ends of a continuum along which neurology and psychiatry merge into one another. Present tests of brain function are crude. As better indicators of brain activities are developed, so will dysfunctions become more reliably evident. Better attention to controls and to sampling would also reduce the current discrepancies of opinion.

Links with specific neurological conditions

Encephalitis and encephalopathy. There were many reports of obsessive-compulsive symptoms accompanying encephalitis lethargica in the years following the pandemicity of this condition after World War I (e.g. Bender, 1935; Brickner, 1940; Schilder, 1938). The phenomena included counting and other rituals, and obsessive thoughts. They often occurred in short bursts lasting a few minutes, and might be accompanied by oculogyric crises, anxiety and aggression. Many of these patients had developed Parkinson's disease, suggesting impairment of the basal ganglia and substantia nigra. There were no neuropathological differences between encephalitics with and without obsessive-compulsive symptoms. Compulsive counting without anxiety but with psychic akinesia was described in two patients with encephalopathies who had bilateral necrosis of the globus pallidus, one following a wasp sting and the other following carbon monoxide poisoning (Laplane *et al.*, 1984).

Parkinson's disease. Obsessive traits (not symptoms) are frequent in Parkinsonism (Trimble, 1981), but Parkinsonism is usually a disorder of the elderly, whereas OCD mainly affects young adults. Perhaps paradoxically, oral levodopa for Parkinsonism occasionally produces obsessive-compulsive symptoms as a side effect (Yaryura-Tobias & Neziroglu, 1983).

Diabetes insipidus. This is a rare association. A case of Parkinsonism, diabetes insipidus and compulsive behaviour was described by Courtney (1928). Five of nine cases described by Barton (1965) had OCD in addition to excess drinking; one had a pinealoma and another was post-encephalitic. According to Barton (1976) either the diabetes insipidus or the OCD could start long before the other began. Vasopressin did not relieve the obsessive-compulsive symptoms (Barton, 1976). One study found more history of *neurological disorder* in OCD than in other neuroses, but the label of 'neurological' was swelled by peripheral problems

such as diphtheria, herpe zoster and Bell's palsy (Grimshaw, 1964).

Head injury. Head injury was followed by OCD in 3% of 415 cases reported by Hillbom (1960), but in only 0.3% of 670 cases studied by Lishman (1968). Four cases of OCD were reported by McKeon *et al* (1984), in whom the symptoms began shortly after the head injury – in one case within 24 hours.

Birth injury. A history of birth injury was found in a third of 33 patients with OCD, more than in other psychiatric patients (Capstick & Seldrup, 1977). However, only one of the obsessive-compulsives had physical signs of brain damage. These authors noted that the patients with a birth injury tended to have more 'bizarre and magical' rituals.

Epilepsy. Links between OCD and epilepsy have been noted in a trickle of case reports. Napoleon had epilepsy and a compulsive ritual of counting the number of windows in the buildings he passed. This century has seen a few case reports. Two patients developed petit mal a few months after first showing obsessive-compulsive symptoms (Pacella *et al*, 1944). Another subject developed typical OCD when *grand mal* fits stopped suddenly after 15 years (Garmany, 1947). The present paper describes two cases of OCD which began just after the new onset of epilepsy, the fits in one coming from the temporal lobe. Gibson & Kennedy (1960) describe one woman in whom the spike and wave discharges on EEG would increase when her obsessive-compulsive symptoms became worse. Stereotyped thoughts or forced thinking have been described as part of an epileptic aura (Penfield & Jasper, 1954), and obsessive-compulsive symptoms may appear briefly during the aura of a fit associated with temporal lobe pathology or reappear transiently in the postictal phase (Brickner *et al*, 1940). Further cases of epilepsy with ictal or interictal obsessive-compulsive symptoms were noted by Yaryura-Tobias & Neziroglu (1983).

Obsessive personality traits are frequent in the general population, so it is hardly surprising that they are also found in some epileptics. Guerrant *et al* (1962) found that they occurred no more often than in other patients with chronic illnesses.

Other considerations

EEG abnormalities in OCD. Varying rates of EEG abnormalities in OCD have been reported, ranging

between 11% and 65% (Bingley & Persson, 1978; Ingram & McAdam, 1960; Inouye, 1973; Insel *et al*, 1983; Pacella *et al*, 1944; Rockwell & Simons, 1947; Sugiyama, 1974). The EEG abnormality may be most marked over the temporal lobes either in a waking state (Jenike & Brotman, 1984) or during sleep (Epstein & Bailine, 1971). Visual evoked potentials have been reported as abnormal (Ciesielski *et al*, 1981; Beech *et al*, 1983). According to Shagass *et al* (1984) the pattern of the evoked potential in 14 obsessive-compulsives could be distinguished from the pattern in other neurotics and schizophrenics. The sleep EEG in OCD sufferers differed from that of controls, but was similar to the EEG of age-matched depressives (Insel *et al*, 1982; 1984). Among adolescents who had OCD and a history of major depression, the sleep EEG also resembled that of young adults with primary depression (Rapoport *et al*, 1981). Flor-Henry *et al* (1979) described eleven patients with OCD who had left frontal lobe dysfunction shown by abnormal EEG variability and neuropsychological impairment. However, such abnormalities in the EEG and similar tests were not found by Insel *et al* (1984) in 18 cases of OCD. In children with OCD, EEG abnormalities were uncommon, mild and non-specific (Flament & Rapoport, 1984), although they had deficits on neuropsychological tests similar to those in frontal lobe lesions.

CT scan changes in OCD. Flament & Rapoport (1984) reported increased ventricular size in children with OCD. Sixteen adolescents with OCD had a higher mean ventricular:brain ratio (and more spatial perceptual deficits) of frontal type than did matched controls (Behar *et al*, 1984). Other studies (Rapoport *et al*, 1981; Insel *et al*, 1983) noted no changes in adults with OCD.

Psychosurgery. Relief of OCD after psycho-surgery indicates some of the pathways that can partly mediate the problem, though they may well be downstream from its origin. Benefit has followed surgical lesions the orbital frontal cortex, anterior cingulum and related areas. In 334 patients with OCD from 12 series (reviewed by Yaryura-Tobias & Neziroglu, 1983, p197) 54% improved markedly and a further 24% improved moderately after various psychosurgical operations. Further evidence of improvement in OCD after surgery was reviewed by Marks (1986).

Electrical stimulation of the brain. Relevant information has been yielded by electrical stimulation of

the brains of subjects without OCD. In one woman, area 6 on the medial side of the left hemisphere was stimulated repeatedly while she recited the alphabet (Brickner, 1940). Whenever she was being stimulated the patient would repeat the same letter over and over again. This perseveration ceased instantly when the stimulation was stopped. The areas were then excised, but pathological examination detected no abnormality. Different movements – sucking, palpation or nibbling – were evoked in 52 epileptics during electrical stimulation of certain sites in the anterior cingulum (Talairach *et al.*, 1975). The patients experienced these movements as involuntary and forced on them, as occurs with compulsive rituals. Unlike rituals, however, the movements were associated with euphoria and not anxiety, were not repetitive, and were less complex.

Conclusions

Rare cases of obsessive compulsive disorder have been reported after lesions of the hypothalamus, third ventricle and basal ganglia. A handful of obsessive-compensatives had diabetes insipidus. OCD occasionally accompanies epilepsy, as in the two cases described in the present report. Stimulation of area 6 on the medial side of the left hemisphere has led to perseveration in one case. Surgical lesions of

the anterior cingulum and frontal areas can improve severe and intractable OCD. Such data indicate pathways that can mediate occasional obsessive-compulsive symptoms. These pathways, however, could be well downstream from the usual mechanisms that initiate and maintain OCD, and precise understanding of them is still a long way off. Most cases of OCD have no organic pathology detectable by present methods; there is great disagreement about the proportion who have abnormal EEGs or psychological tests or a history of brain injury.

The evidence for neurological factors therefore remains 'tantalizing' (Elkins *et al.*, 1980) but inconclusive. Newer tools such as the positron emission tomography scan or neurotransmitter studies might unlock further secrets of this elusive disorder. However, aetiology and treatment need not go hand-in-hand. Despite the neurological factors seen in some obsessive-compulsive patients, most cases of OCD improve markedly and lastingly with behavioural treatments (Marks, 1986), although this was not true for the 2 cases of epilepsy we report – perhaps their anti-ictal drugs or their brain dysrhythmias disrupted learning.

The Dexamethasone Suppression Test in Generalised Anxiety Disorder

E. E. SCHWEIZER, C. M. SWENSON, A. WINOKUR, K. RICKELS and G. MAISLIN

The dexamethasone suppression test was performed on 79 patients with a diagnosis of generalised anxiety disorder. A non-suppression rate of 27% was obtained, comparable to that found in out-patient major depression but notably higher than previous reports in panic disorder. No good clinical predictors of non-suppression were discovered, nor was the co-occurrence of depression sufficient to account for the finding.

The dexamethasone suppression test (DST) has become the most widely applied neuroendocrine measure in depression research. Non-suppression of cortisol has consistently been reported to occur in 40-50% of in-patients suffering from endogenous depression (Carroll, 1982). Reports of non-suppression rates for out-patients have been lower, ranging from 15-25% (Winokur *et al*, 1982; Amsterdam *et al*, 1982; Rabkin *et al*, 1983). Claims for the specificity of DST non-suppression range around 95% (Carroll, 1982), but recent reports suggest significant non-suppression in other psychiatrically ill patients (Dewan *et al*, 1982; Castro *et al*, 1983; Targum, 1983; Coppen *et al*, 1983; Raskin *et al*, 1982) and normal control subjects (Winokur *et al*, 1982; Amsterdam *et al*, 1982; Coppen *et al*, 1983; Hallstrom *et al*, 1983).

Anxiety states are the disorders most closely linked to depression. Recent studies of family history (Crowe *et al*, 1983) and of the course of illness (Leckman *et al*, 1983) suggest a partially shared diathesis. There is also a suggestion that antidepressant drugs may have a therapeutic effect in the treatment of certain types of anxiety states (Sheehan *et al*, 1980; Klein, 1984) and that anxiolytics may be efficacious in endogenous depression (Feighner *et al*, 1983).

Three studies (Curtis *et al*, 1982; Lieberman *et al*, 1983; Sheehan *et al*, 1983) have reported on cortisol response to dexamethasone challenge in anxious patients. All three studies were restricted to the DSM-III diagnosis of agoraphobia with panic disorder (American Psychiatric Association, 1980), and all reported rates of DST non-suppression that were comparable with normal controls. The present study examines the cortisol response to dexamethasone in a group of patients suffering from generalised anxiety disorder.

Method

A group of 47 women and 32 men with a diagnosis of generalised anxiety disorder was studied; their ages ranged from 21 to 61 years, with a mean of 41.2 (sem = 1.30). The patients were self-referred to the Psychopharmacology Research Unit at the Department of Psychiatry, University of Pennsylvania, for treatment in a double-blind drug trial. All patients were diagnosed by a trained research psychiatrist, employing a standardised psychiatric interview based on DSM-III criteria. Patients with depressive disorders or other Axis I diagnoses were excluded. Two research psychologists administered the Schedule for Affective Disorders and Schizophrenia, Lifetime version (SADS-L; Endicott & Spitzer, 1978) to a random sample of 31 of the 79 patients. The psychologists were blind both to clinical diagnosis and to whether the patients were to enter a depression or anxiety treatment protocol.

The Hamilton Anxiety Scale (HAS), Raskin-Covi Scale and the Hopkins Symptom Checklist-90 (HSCL) were completed on all patients. A physical examination was carried out, and patients excluded if they had acute medical problems, a history of alcohol or drug abuse, were on concurrent psychotropic medication, or had an HAS score of less than 18 or a Raskin Depression score greater than 8. No patient met the exclusion criteria for DST (Carroll *et al*, 1981). Freedom from psychoactive medication for seven days prior to entry was confirmed by a urine drug screen in all patients.

Each patient was instructed to take 1 mg of dexamethasone orally at 2300 hrs on the night before their next clinic appointment. Blood was taken for plasma cortisol determination between 1200 and 1700 hrs; plasma cortisol concentration was measured as described by Amsterdam (1982). Cortisol cut-off values of both 4.0 µg/100 cm³ and 5.0 µg/100 cm³ were used to determine non-suppression. Chi-squared, Mann-Whitney, and one-tailed and two-tailed *t*-tests were used in the analysis of the data.

Results

Twenty-one of the 79 patients (27%) who met the criteria for generalised anxiety disorder were non-suppressors,

using the $4.0 \mu\text{g}/100 \text{ cm}^3$ cut-off, and 19 patients (24%) were non-suppressors on the basis of a cut-off of $5.0 \mu\text{g}/100 \text{ cm}^3$. The mean post-dexamethasone cortisol value for the non-suppressor group was 9.1 (sem=1.4) compared with $2.5 (=0.5) \mu\text{g}/100 \text{ cm}^3$ for suppressors. A blind SADS-L evaluation of a random sample of 31 of the patients confirmed the clinical diagnosis in all but three of the DST suppression subjects (revised diagnoses were one panic disorder, one atypical anxiety, and one generalised anxiety disorder with concurrent major depression) and in all but one of the DST non-suppressors (revised diagnosis: panic disorder).

Examination of differences in patient characteristics between the non-suppressor and suppressor groups was undertaken; five of the 32 men (16%) and 16 of 47 women (34%) were non-suppressors ($\chi^2=2.43$, NS). Pooled *t*-tests revealed no statistically significant differences in the ages, heights, or weights of the two groups. The scores on the individual items of the HAS and the HSCL were analysed for significant differences between suppressors and non-suppressors using the Mann-Whitney and an $\alpha=0.05$ significance level. On the HSCL, non-suppressors differed from suppressors for poor appetite, fearfulness, feeling nervous when left alone, absence of paraesthesias, and absence of feeling tense or keyed-up. On the HAS, the item relating to somatic (muscular) symptoms was significantly higher for non-suppressors. HSCL items were then grouped into the five factors, and pooled *t*-tests used to test for significant differences in the means between the suppressor and non-suppressor groups. None of the factors achieved significance, although there was a trend toward significance for the somatic factor ($P=0.06$) and the depression factor ($P=0.08$). Raskin depression scores also revealed no significant differences.

Discussion

The main finding of this study is a 27% rate of cortisol non-suppression after dexamethasone administration in out-patients suffering from generalised anxiety disorder; this is comparable to rates for out-patient major depression (Winokur *et al*, 1982; Amsterdam *et al*, 1982; Rabkin *et al*, 1983). This rate of non-suppression contrasts sharply with the low rate of abnormal DST results reported in three studies (Curtis *et al*, 1982; Lieberman *et al*, 1983; Sheehan *et al*, 1983) of patients with panic disorder. Curtis *et al* tested 20 patients with panic disorder, both with and without agoraphobia, and found three out of thirteen (23%) abnormal results in patients with agoraphobia and panic; they noted that two of the DST non-suppressors were in an alcohol withdrawal state, and that the other had a concurrent major depression. None of the other seven panic disorder patients without phobic avoidance had abnormal results. Lieberman *et al* reported

no abnormal results in ten panic patients, though the patients in this study had been premedicated prior to the test with diazepam (2–10 mg) or lorazepam (2–6 mg). Sheehan *et al* (1983) reported 4 out of 51 (8%) abnormal results in a sample of agoraphobics with panic disorder. In agreement with these three studies, we have found only one case of DST non-suppression in 11 patients with panic disorder.

Some explanations for the relatively high rate of dexamethasone non-suppression in generalised anxiety disorder must be considered. Firstly, it is possible that some patients were non-compliant with regard to dexamethasone administration, but the high level of co-operation with the other aspects of the out-patients drug treatment argues against this. Time of blood sampling is known to affect cortisol results, but sampling was usually done earlier than the conventional 1600 hrs, and therefore may have reduced rather than increased the incidence of non-suppression. The co-occurrence of depression might be a diagnostic artifact and explain the high levels of non-suppression in this sample. Blind SADS-L confirmation of clinical diagnoses makes the covert presence of syndromic levels of depression unlikely. At a subsyndromic level, three indices of severity of depression can be applied: the depression item on the HAS and the Raskin score on the Raskin-Covi scale both yielded non-significant differences between suppressors and non-suppressors, while the self-report depression factor on the HSCL only achieved a significance of $P=0.08$. Overall, it is unlikely that depression accounted for a large measure of the DST non-suppression.

Lastly, the data were examined for predictors of non-suppression. All of the HSCL individual items, HSCL factors, and HAS items were analysed for significant differences. Not surprisingly, there were some significant predictors of non-suppression in the HSCL items, but no more than would be expected to occur randomly, and none that matched our predictions. Sex did seem to have some effect, since females showed a trend for a high rate of non-suppression ($P=0.07$).

In summary, a sample of patients with generalised anxiety disorder was found to have a rate of DST non-suppression that was comparable to that found in out-patient major depression. This was in contrast to a much lower rate of non-suppression observed in studies of patients with panic disorder. No good clinical predictors of non-suppression were discovered, nor was the co-occurrence of depression enough to account for the present finding. Further studies of DST in generalised anxiety disorder patients need to be undertaken, both to confirm this result and to shed more light on its implications.

Psychotherapy for Victims of Torture

F. E. SOMNIER and I. K. GENEKKE

Three groups of torture victims were studied with the aim of establishing a concept of psychotherapy for such victims. Analysis of the first group, consisting of 200 case-reports made by Amnesty International medical groups, resulted in a general outline of the psychological methods of torture and their main impact on the victims. A second group of 24 torture victims was examined by the authors, and a quantitative assessment of long-term neuropsychological complaints and a qualitative insight into these symptoms achieved. In-depth interviews with victims in the third group which, consisted of the victims from the second group and six others, together with the results from the other two groups, formed the basis of a concept of psychotherapy for torture victims.

Exposure to extreme situations may cause physical and psychological sequelae. This has been abundantly documented for former concentration camp prisoners (Kral *et al*, 1967; Strom, 1968; Nefzger, 1970; Thygesen *et al*, 1970; Beebe, 1975) and naval personnel (Askewold, 1980) after the Second World War. Similar findings have been reported with hostages (Eitinger & Weisaeth, 1980).

Amnesty International medical groups have described many such complaints in torture victims from a number of countries (Amnesty International, 1977, 1978, 1980, 1981; Randall *et al*, 1986). The initial aim was to provide proof, from the point of view of forensic medicine, of the existence of torture. The same reports also provide evidence that the sequelae of the clandestine torture of today are of the same magnitude as those reported for concentration camp victims. Furthermore, it can be inferred that there is little or no tendency to spontaneous recovery. This topic is therefore a concern of the medical and psychological professions.

Different views upon the aetiology of the sequelae of concentration camp survivors are reflected in the different terminology of the various syndromes (Strom, 1968; Thygesen *et al*, 1970; Trautman, 1964; Lederer, 1965; Krystal, 1968; Niederland, 1968; Hoppe, 1971). The discrepancy between the American psychodynamic views and the European more organic oriented explanations may be due to the fact that highly selected but very different groups were investigated (Eitinger 1986).

As pointed out by Lederer (1965), classical German psychiatry stated that life experiences, no matter how severe provided they do not inflict organic brain damage, can never cause lasting symptoms or alteration of personality. A similar

point of view was alleged by Wolff (1960) in his paper on the conduct of prisoners-of-war. The interpretation by laymen may be the same. Also, victims of torture may consider themselves responsible when mental disability results from the cruelty. According to this hypothesis, psychological sequelae arise from a constitutional susceptibility, and psychological complaints can be seen as wishful reactions with the aim of maximal gain. The admission of psychological sequelae may thus imply a stigma, and the symptoms may be denied for years without motivation for treatment. Klein (1974) described the same therapeutic paradox in his work with survivors of the concentration camps.

On the other hand, Trautman (1964) stated that human beings placed under extreme and prolonged existential stress, fear and anxiety undergo an extensive adaptive change of mental and biological functioning. This point of view is supported by Bettelheim (1943). Adaptive change in psychiatric patients submitted to an authoritarian institution is described by Goffman (1961). Trautman's conclusion was that psychological sequelae should be seen as meaningful conditioned reactions for a sound and forceful constitution that make survival possible in a very pathological situation.

In this study the various psychological methods of torture and the long-term neuropsychological symptoms are evaluated to assess the adaptation of torture victims and to establish a concept of psychotherapy for them.

Method

This study is based on an analysis of three different groups of torture victims. The term 'torture' is used in accordance

with the definition of the World Medical Assembly (The Declaration of Tokyo, 1975): the deliberate, systematic or wanton infliction of physical or mental suffering by one or more persons acting alone or on the orders of any authority, to force another person to yield information, to make a confession, or for any other reason.

Group 1. Two hundred case reports from Amnesty International medical groups, based on semi-structured interviews and medical examination of torture victims, formed the background for a systematic outline of the psychological methods of torture. All reported methods of torture were analysed with the aim of obtaining a more general knowledge of the actual procedures and their main impact on the victims. Ninety-five percent of the victims were males, and most of them were exiles at the time of study. The group consisted of victims from Latin-America, Europe, Africa and Asia.

Group 2. Since 1981 a large number of torture victims have been examined thoroughly at the Department of Neurology, Rigshospitalet, Copenhagen. Among them were 24 victims from different Latin-American countries. Long-term neuropsychological complaints from this group were analysed with regard to time since first exposure to torture. Ten of the victims had previously been examined by the Amnesty International Danish Medical Group using the same semi-structured interview as in the present study; the complaints of these victims were used as the basis for a follow-up comparison. All victims were males and exiles. All were in perfect health before exposure to torture.

Group 3. This group consisted of the 24 victims from group 2 plus four European and two African victims. Twenty-nine of the victims were males, and most of them were exiles at the time of study. The method of psychotherapy has been worked out from observations and systematic notes made by the authors during 425 in-depth interviews with these 30 torture victims since 1981.

All of the victims in this study were selected, and no control group was included. The victims examined by Amnesty International medical groups volunteered for medical investigations within the scope of forensic medicine, epidemiology, and clinical nosography. The victims examined by the authors volunteered for an in-depth investigation of physical and psychological sequelae to torture with the aim of establishing rehabilitation programmes.

Results

Psychological methods of torture

Although an over-simplification, the procedures can be divided into two types: the weakening techniques and the personality-destroying techniques. Common to the methods of the former is teaching the victims to be helpless and creating exhaustion. The latter methods are characterised by the induction of guilt, fear and loss of self-esteem.

Deprivation

Deprivation is defined according to Schultz (1965). A variety of procedures have been used to reduce environmental stimulation, and as a rule the victim is submitted to

different forms of deprivation at the same time. During deprivation the victim suffers from cognitive disturbances, disorientation in time and space, difficulty in concentration, poor memory, and in some cases psychotic reactions with hallucinations. Long-term sequelae may be weakening of identity and emotional instability.

Constraint techniques

These are defined as psychological techniques which force experiences and stimuli upon victims which are totally foreign and harmful to their personality and conduct. Victims are submitted to a detailed set of regulations and rules, resulting in close supervision where everything (including completely insignificant details) is controlled. Violation of the rules (either real or supposed) is used as an excuse to punish the 'offending' victim. The victims are exposed to all kinds of humiliations, which force them to see their dignity and identity completely destroyed.

Induction of incongruent actions, i.e. methods which bring the victims into situations of impossible choices and consequently to act or react against their ideology and ethics, seems central to all psychological torture. Included are methods with the classical aim of yielding information, but it should be emphasised that in many cases this is a sham-purpose, with the real goal being to destroy the personality of the victim. The technique may be slow and progressive, starting by letting the victim admit insignificant or diffuse items; gradually, more specific information is disclosed. When the victim eventually breaks down he enters a vicious circle of guilt followed by repentance, which cannot be expiated. Other methods are mock-executions and threats of torturing family or friends if the victim does not fulfil various demands. African victims have reported violation of taboos as a method of torture.

The effects of the constraint techniques are multiple and long-lasting. The methods represent deep attacks on the identity and dignity of the victim, and they are closely linked with guilt, fear, loss of self-esteem, and repentance. During torture and imprisonment the aggressions of the victim are by necessity turned inwards, and there is no possibility of adequately expressing emotions. As time goes by the events may to an extent be repressed, leaving a feeling of discontinuity in the victim's personality. Some of the experiences are remembered as profound humiliations. Other experiences become an unconscious source of suffering due to a feeling of guilt.

Communication techniques

There are a variety of verbal and non-verbal communication techniques, with varying aims. Counter-effect technique, for example, is defined as torture which seems meaningless to the victims and which continues whether or not the victim co-operates. Any response from the victim becomes the pretext for renewed or continuous torture. The victim's aggressiveness and ability to fight back gradually decrease, and thus the victim learns to be totally helpless.

Double-bind techniques are frequently abused as torture. The term 'double-bind' originates from Bateson's hypoth-

esis about schizophrenia. Victims are exposed to many ambiguous situations and contradictory messages, which induce confusion. Seemingly nice suggestions by the torturers soon turn out to be false, and promises to victims are broken in the next moment. A well-known technique involves the use of a friendly and a unfriendly interrogator. After violent torture carried out by torturers of low rank, the victim is interrogated by an officer of high rank in an ambience of tranquillity and polite conversation. Simultaneously, the officer intimates that he would hate very much to have to hand over the victim for further violence. In a situation of deep distress it is difficult for the victim to resist and not to grasp a 'helping' hand.

Conditioning technique was first described by Pavlov in his experiments with dogs, and the principle is to induce desired reactions or behaviour by certain conditions. As torture, the conditioning techniques are abused to adapt the victims to various demands.

Abuse of pharmacology and psychiatric institutions

There are many examples of these kinds of abuses as methods of torture. Such methods imply the abuse of the medical and psychological professions. The goals are various: profound mental destruction, punishment, creation of anxiety and psychological disturbances, causation of pain, immobilising victims, and yielding information. The psychopharmacological drugs abused either blunt the senses (neuroleptics or sedatives) or are psychotropics, including hallucinogens. Neuromuscular blocking agents (curare compounds) are abused to paralyse fully-awake subjects, which induces total panic due to the impossibility of breathing, and the victims are not offered oxygen until the point of suffocation. If victims are defined as 'mentally ill' they can be admitted to psychiatric institutions and submitted to various 'treatments' against their will, including psychopharmacological drugs.

Physical methods

Physical methods of torture are administered by physical means, but their main impact is of a psychological nature. Because of the acute and chronic pain evoked by such torture, one of the sequelae may be a distortion of the body image.

Long-term neuropsychological symptoms

The investigation of the 24 torture victims in group 2 was carried out a median of 9.5 years (range: 7.5–11.5) after the first exposure to torture. The median age of the victims was 38 years (range: 28–42). The previous examination of 10 of the victims had been performed a median of 3.9 years earlier (range: 2.5–5.5).

Table I shows the frequency of neuropsychological complaints, arranged in decreasing order. There are no obvious differences in symptoms at the two examinations; nor are there if the 10 victims previously examined are compared only with themselves (not shown in the table). The investigation thus provides evidence of a poor tendency to spontaneous recovery. The number of victims is inadequate for any statistical evaluation; the quantitative aspects of the symptoms will not be further described.

TABLE I
Neuro-psychological complaints

<i>Complaints¹</i>	<i>Present study (n=24)</i>		<i>Previous examination (n=10)</i>	
	<i>%</i>	<i>n</i>	<i>%</i>	<i>n</i>
Sleep disturbances	83	20	60	6
Headache	79	19	80	8
Impaired memory	79	19	60	6
Impaired concentration	75	18	60	6
Fatigue	75	18	60	6
Nightmares	71	17	60	6
Fear/anxiety	50	12	40	4
Impaired hearing	38	9	40	4
Social withdrawal	38	9	50	5
Vertigo	33	8	20	2
Sexual disturbances	21	5	20	2
Tremor/shaking	13	3	20	3

1 Five (21%) of the victims investigated in our study suffered from guilt. This complaint was not systematically asked for.

The complaints have rather particular qualitative characteristics. Perhaps surprisingly, spontaneous hate, hostility, and aggression have not been a common feature. The victim's feelings about the torturers are reflected by the typical statement that the torturers should be prosecuted in accordance with democratic laws. During interviews examiners can sense the victim's inward-turning aggression. In spite of all the suffering and sacrifice, victims often claim that the struggle for social justice will never cease. Much emphasis is laid upon the victim's further education and work and the welfare of the family. We have not in any single case observed that victims identify themselves with the aggressor (the 'Stockholm syndrome', Eitinger & Weisaeth, 1980).

Unlike neurosis, the anxiety of the victims is associated with conscious memories, tentatively but never really fully repressed. The anxiety is evoked by sensory, auditory or visual signals or experiences symbolising torture and persecution. The victims react immediately to the 'signal' and are overwhelmed by panic before they have had time to think. To the observer it is clear that these victims are living on an unconscious alert, as if the previous danger was still present. This panic reaction can be evoked by such things as an automobile door slamming, the sound of a siren, or the sight of a soldier or policeman in uniform. Evoking experiences may be such things as a visit to a small room or lift (the cell is recalled), admittance to hospital and confrontation with equipment or investigations resembling the torture situations (blood samples, ECG, X-ray, etc.), or taking an examination (the interrogation centre is recalled). The same may be the case when a therapist, social worker, employer or any 'authority' addresses the victim in a somewhat unfriendly manner (the person is immediately identified with the torturer).

Sleep disturbances are frequent. One of the main reasons

is a repetitive reliving of the same torture experiences during nightmares in which the subject is trying to escape but is helpless, without means of protecting himself and also without counter-aggression. In the conscious memories of the torture, the victim is aware that the aggression had by necessity to be repressed; in the nightmare, however, there is no attempt at defence, and this may be one of the reasons why these nightly experiences are so evocative of extreme anxiety.

Many victims allege impaired memory and difficulty in concentration. During in-depth interviews we have made no observations consistent with dementia, nor observed progression in the alleged cognitive malfunction. In some cases the behaviour may be marked by decreased vigilance and resistance to taking an interest in outside activities. In spite of the victim's 'poor' memory the experiences of torture are remembered to the smallest detail.

Depression is another common feature. Some victims are less anxious when more depressed and vice versa. Loss of self-esteem and a feeling of guilt are often linked, and during the in-depth interviews these complaints can be traced back to certain experiences during torture. Fatigue, emotional instability, and social withdrawal may be considered as consequences of the other symptoms. Sexual disturbances have not yet been studied in detail.

Psychosomatic complaints are frequent. Chronic diffuse headache, muscular tensions, fear of having heart disease, and dyspeptic symptoms are daily experiences for most victims.

Concept of psychotherapy

The course of psychotherapy for torture victims is divided into 3 phases. The first phase is mainly cognitive, with the aim of bringing about a detailed insight into what really happened and thereby generalising the personal suffering. The second phase is more emotive, with emphasis on a reconstruction of the most harmful experiences gradually bringing the victim in contact with repressed feelings. During the reliving of the feelings the victim has an opportunity to realise that his conduct was not unique, but predictable. In this context the victim must also work with feelings which were naturally present, but which could not be expressed at that time, especially the aggression. The third and final phase serves to re-establish reality by offering the victim a way out of the seemingly endless traumatic state induced by the torture. The principle is to interrupt different vicious circles and to transform much of the energy from the previous fixed role of a victim into creativity, enabling a more dynamic course of life.

To illustrate the method we present a case history. Certain details have been changed to avoid recognition.

Case History

The victim is a 27 year-old Latin-American male. He grew up in a safe and economically solid home together with four siblings. After school he soon qualified as a skilled worker. The victim was considered as a strong person by those who knew him, and he has always reacted against social injustice. There was no previous history of neuro-

psychological problems, and he was in perfect health before exposure to torture. His first imprisonment, at the age of 18, lasted 7 months. The second imprisonment took place 2 years later, and lasted 18 months. On no occasion was he under any charge or put on trial. The victim was exiled after release from the second imprisonment.

During the first imprisonment he was submitted to solitary confinement, placed in a small dark cell without a toilet and almost without food and drink. The warders were extremely brutal, and he was repeatedly beaten up, suspended, whipped and threatened. When he started bleeding, salt was poured on the wounds. His head was battered against the wall until he lost consciousness. This was repeated twice per day during the first 3 weeks. He was sexually abused twice.

During the second imprisonment he was placed in a small room in a cellar, without light or toilet, and with only a dirty blanket for cover. For one month he was exposed daily to electric torture. Current was applied to all parts of his body, but particularly to his testicles, teeth, tongue, and ear-lobes. Several times his head was held in a bucket with water containing vomit and urine until the point of suffocation. Three times he was exposed to mock-executions. Several times he was forced to see other prisoners being tortured, particularly by different kinds of sexual torture.

Five years after release the victim was still suffering from the same symptoms as immediately after torture. He was distrustful and despairing, showing severe depressive features with suicidal thoughts. Panic was evoked by abrupt sounds or when he was confronted with authorities. Chronic headache, impaired hearing in the left ear, poor memory and social withdrawal were other important features. Apathy and fatigue were the consequences of difficulty in falling asleep and interrupted sleep with frequent nightmares.

The victim was offered psychotherapy in combination with a simultaneous physical pain-relieving therapy. The cognitive phase took place during ten in-depth interviews, three per week. When mutual trust was established the therapy proceeded by cognitively reconstructing the harmful experiences. If the victim resisted a thorough description of the experiences in prison, they were approached instead by way of his nightmares. The cognitive context was stressed, consisting of information about the most important goal of the torture: to destroy the personality of the victim. During the conversations, otherwise inexplicable humiliations were viewed within a meaningful relationship, rendering it possible to generalise the personal suffering. The victim felt relief after every interview. There were emotional fluctuations at the end of the first phase. The victim was joyful for some days, making subsequent dives into depression even more painful.

The emotive phase consisted of ten in-depth interviews during a 3-week period. The victim was still suffering from violent nightmares, which provoked intense fear and made the victim depressed for a long time. The most frequent nightmare concerned a mock-execution to which he had been submitted during the second imprisonment. The torturer had placed a bottle on his head, whereupon the

bottle was shot to pieces. The victim awoke abruptly at the moment of dreaming of the shot, totally in panic and helpless. During the victim's detailed description of this nightmare he realised that the most panic-evoking part was his own lack of aggression. Three interviews later he related that the previous night he had experienced the same nightmare. This time, however, he had fixed the eyes of the torturer, who immediately looked at him with respect and was not laughing as usual. At that moment he felt a great strength. During the interview he remembered that for several days after the mock-execution he could hardly believe he was alive. He thus found himself in a situation where the following electric torture was a confirmation of life. Later he felt that he could no longer stand to be tortured constantly, and he begged the torturers to kill him. For some time great care was taken that the victim did not lose consciousness during torture. Thus he found himself in a situation where being forced to live was in itself torture. In subsequent in-depth interviews the method of impossible choices was thoroughly explained to him. It was a great relief for the victim to realise that no matter what he had done, he would have felt that he had made the wrong choice.

When the victim proceeded to the third phase, the re-establishment of reality, there were changing moods from almost euphoria one week to depression the next. On some occasions there were relapses of nightmares, which were evoked by bad news from his country. The interviews took place with intervals of 1–2 weeks. Gradually the victim developed insight into the various vicious circles, and was soon able to circumvent the mechanisms. The victim started helping friends and other victims. He was then, for the first time since release, able to deal constructively with the school problems of his children. Before the therapy his wife had justly accused him of being evasive when confronted with these problems. The victim started supplementary education. One result was that it was no longer necessary for his wife to shoulder a heavy burden, and she could then tell us that she was a torture victim herself with an urgent need for psychotherapy.

After 28 in-depth interviews over 4 months the therapy was stopped, with an agreement that the victim could apply again if he wanted further treatment. During a follow-up period of two years there has been no subjective need for resumption of psychotherapy. At the end of that period an in-depth interview confirmed that further treatment was unnecessary.

Other cases

The psychotherapy was performed according to the same principles in the other 29 cases. A median number of 22 in-depth interviews were needed (range: 10–52). The whole procedure was carried out during a median period of 12 weeks (range: 4–19). In our hands the method has been successful, with only a few relapses during a median follow-up period of 11 months (range: 6–36 months). When supplementary psychotherapy was needed, 2–3 sessions were generally sufficient. It must be emphasised that during the period of psychotherapy a pain-relieving physical therapy was simultaneously carried out.

Discussion

The psychological methods of torture listed above provide evidence that normal psychological mechanisms are distorted by torture and that torture is performed in a systematic and scientific way. Destruction of the personality of the individual victim is probably one of the most important goals of torture.

An important biological character of the brain is the great capacity for adaptation. One would expect the victims to adapt to the atrocious circumstances with the aim of preserving as much as possible of their personality, including norms, ideology and emotional reactions. There are two other 'possibilities': biological or psychological death—suicide or psychosis. Bettelheim (1943) observed the adaptation procedure of concentration camp prisoners, and Goffman (1961) described adaptation to an authoritarian institution. Between them they describe four coping strategies: intransigence, re-establishment, introversion, and conversion. Eitinger (1974) found during interviews with more than 2000 concentration camp survivors that one of the most important coping mechanisms was the conservation of the ability to make at least a few of one's own decisions. Those who were able to retain their system of values and personality more or less intact were the most fortunate, i.e. people who could practice and show interest in others (doctors, nurses, priests, social workers, etc.). Identification with the aggressor was used by some, but this mechanism led to deep pathological changes in the personality. A few had maintained an attitude of a detached observer, but this mechanism was unsuccessful due to the loss of contact with others and with reality. Eitinger's conclusion was that survivors who mobilised an active and more or less conscious coping mechanism had fewer psychiatric complications than survivors who were completely isolated, remained passive, or ascribed survival to mere luck.

Short-term neuropsychological complaints provide evidence that torture victims adapt to the inhuman conditions (Amnesty International, 1977, 1978, 1980, 1981). The 200 case reports from Amnesty International medical groups in the present study provide no evidence for the use of a strategy of conversion, and an intransigent attitude was rarely maintained for a significant time. This has been confirmed during the 425 in-depth interviews with the third group of torture victims studied, so presumably those mechanisms are rarely used by torture victims. On the other hand, the same two studies provide evidence for a frequent use of a strategy of introversion and re-establishment.

The various physical sequelae reveal the applied physical torture (Genefke & Aalund, 1982). Perhaps more surprisingly, the long-term neuropsychological symptoms (Table I), and particularly the qualitative aspects, are evidence of a long-term adaptation to a victim's role, where previous danger is still experienced or easily evoked. There is thus an element of a faulty accordance with reality. Furthermore, the tendency to spontaneous recovery from the neuropsychological complaints seems poor.

Out of this concept of the psychological sequelae as a result of specific and systematic psychological methods of torture, adaptation to atrocious circumstances, vicious circles of anxiety, guilt, repentance, atonement, and loss of self-esteem, we propose a psychotherapeutical approach to bring the subject out of this victim's role, thus enabling him to restore reality and re-establish a valuable course of life. Forgetting is not the answer; nor is atonement through obsessive remembering.

Psychotherapy for victims of torture requires a thorough reconstruction of the harmful experiences during in-depth interviews, where the methods of torture and the conduct of the victim are evaluated as cause-and-effect situations, not as phenomena. In contrast to classical psychotherapy, the therapy of victims can start as soon as a mutual trust is established, and a preceding period of analysis is unnecessary. In the cognitive phase the victim realises how the torture distorted normal psychological mechanisms, and that the torture was systematic with very particular goals (often different from what the victim thought were the goals). When he realises that these goals were obtained, not because of an inborn weakness, but as a predictable result, the heavy burden of responsibility is justifiably transferred to the torturers.

The cognitive phase is followed by a phase where the most harmful experiences are reconstructed in a more emotional context, enabling the victim to see that there were no options. It is of the utmost importance that the therapist is never identified with the aggressors. The ambience must be characterised by mutual and complete trust. The therapy takes place in an atmosphere of humanity, but with directness and professionalism without unnecessary sentimentality. All procedures which may cause uncontrollable pain and memories are systematically avoided. Precise information about all aspects of the examination and therapy must be given, and the subject must fully understand and accept the procedures. Finally, the therapy must be carried out at a tempo adjusted to the immediate emotional reactions of the subject, and enough space must be allowed between the sessions that the subjects cogni-

tive acceptance and emotional reactions correlate.

Implicitly, the victim realises during the first two phases of the therapy that there is no reason for a general mistrust, and when both a new cognitive and emotional context are achieved the re-establishment of reality is not troublesome.

If a victim has strong repressive mechanisms he is asked to tell his story in chronological order. The victim must describe precisely what he experienced during isolation and the time spent waiting for torture. If these topics (e.g. size of the cell, noises, light, food, toilet facilities, hallucinations) are not probed into, the victim will usually not tell much about them. The victim's reactive pattern often shows itself most clearly when these experiences are described, and this is thus a good starting point for a dialogue about a variety of the victim's psychological mechanisms. The principle of forcing a victim into a conduct totally opposed to his personality and thereby creating guilt and repentance is thoroughly expounded.

During discussions of the situations in which the victim was forced to make a choice, and feels that he made the wrong choice, it can often be proved that no matter what decision was taken the result would have been the same. As a rule the victim has not considered this, and it is a relief to understand how the method of impossible choices has been exploited. Furthermore, it is emphasised that a victim cannot have responsibility for what he did in a situation of utmost physical and psychological pain. The methods are elaborated with the purpose of creating a guilty conscience, and the responsibility lies completely with the repressive system. This principle should be recognised by international law.

By penetrating the most painful experiences the victim has an opportunity to work with them within a new context. During this kind of conversation the victim often realises that he has turned all aggression against himself, even though it should be directed at the torturers. Humiliations must be discussed point for point. Hereby the victim conceives that it is actually the torturers who are degraded by their inhuman conduct. The memories no longer cause the victim the same fear as before, when he eventually comes to understand what was done to him and that he was broken down in a predictable way by torture distorting normal psychological mechanisms.

There are many sources of guilt besides those already mentioned. Some victims consider that they did not help fellows enough during imprisonment, for example, the difficult situation of the family, the many years without education, the present social situation and the very fact of being alive are other examples. It is emphasised that it is the opposite of

egoism and very valuable to mankind that people are willing work for a better society even under very difficult conditions.

The results of the psychotherapy obtained so far have been encouraging. The present study provides evidence that the long-term neuropsychological symptoms may be reversible provided psychotherapy is applied rather than supportive treatment or teaching the victims to cope better. The concept of psychotherapy will be further evolved and evaluated at the International Rehabilitation and Research Center for Torture Victims in Copenhagen.

Rehabilitation of torture victims has to include spouses and children, and indeed the whole social

network of the victims must be taken into consideration. Psychological disability due to exile is also of great significance. However, all of these topics are outside the scope of this paper.

The rehabilitation of a torture victim cannot be considered to have succeeded until the term 'victim' no longer signifies the subject as adapted to this role and instead signifies only a historical event.

Applied Relaxation Training for Generalised Anxiety and Panic Attacks:

The Efficacy of a Learnt Coping Strategy on Subjective Reports

N. TARRIER and C. J. MAIN

The results of applied relaxation training in patients with generalised anxiety and panic attacks are reported. ART was taught during one session, by means of participant demonstration, written instructions, taped instructions, or a combination of all three, with instructions to practise at home. All four methods proved superior to a waiting list control, but there were no differences between the treatment groups. There was some evidence for the non-specific effect of expectancy, but this did not completely explain the treatment effect.

The treatment method of progressive Relaxation Training was designed by Jacobson (1938). During the early development of behaviour therapy it became incorporated into the procedure of systematic desensitisation, as a response incompatible with anxiety (Wolpe, 1958). More recently, however, relaxation has been used (as originally suggested) as a treatment in its own right, and numerous conditions such as hypertension, headaches, insomnia, and anxiety disorders have been shown to be suitable for such treatment (Rachman & Wilson, 1980). Anxiety disorders have been investigated in most detail, and relaxation training is reported to be superior to control procedures. It was typically effective when taught for four or more sessions, when instruction was given in person, and when subjects had control over the progress of treatment (Borkovec & Sides, 1979; Hillenborg & Collins, 1982). Use of a counter-demand condition indicates that the treatment effect of relaxation cannot be explained purely by non-specific effects (Steinmark & Borkovec, 1974; Borkovec *et al*, 1978).

Relaxation training may facilitate fear reduction during exposure treatment of situational anxiety (Gillan & Rachman, 1974), though Glaister (1982) concluded that the fear-reducing effect of relaxation alone was less than that of exposure to the feared stimulus. However, in generalised anxiety states where no precipitating situation can be identified *in vivo* exposure is not possible, and relaxation training may then be indicated for reduction of anxiety. Suinn & Richardson (1971) developed anxiety management training (AMT) for such generalised anxiety conditions: patients were taught to control anxiety through muscle relaxation and mental imagery. Although two studies indicated positive results in

student volunteers (Edie, 1972; Nicholetti, 1972), generalisation to a clinical population may not be valid. However, a recent study (Jannoun *et al*, 1982) reports treatment of 27 out-patients using a modified version of AMT. Patients were allocated to three groups, with a four, six or eight week waiting time. Improvement occurred on all anxiety ratings over the treatment period, and these gains were maintained at three months: significantly greater changes for the groups with less waiting time indicated that the improvement was due to treatment. Furthermore, depression ratings also decreased over this period, and intake of anxiolytic drugs decreased by 60%.

In AMT the therapist assumes a didactic role in helping the patient to acquire a coping skill, and this is in accord with the recent direction of behaviour therapy. However, if the patient is to learn a skill, practice is required. Hillenborg & Collins (1983) demonstrated the superiority of home practice relaxation over no such practice in volunteers, but the same authors (1982) found that only 60% of studies reported any type of home practice, and only 19% assessed compliance. A number of studies indicate that subjects exaggerate compliance, although results correlating subjective and objective compliance with outcome are inconsistent (Hillenborg & Collins, 1983; Hoelscher *et al*, 1984; Barr Taylor *et al*, 1983).

The behaviour literature has been less concerned with aetiology than with the outcome of treatment, but it has been suggested that hyperventilation may play an important role in panic attacks (Lum, 1976; Hibbert, 1984), and breathing control effectively reduces anxiety attacks (Kraft & Hoodguin, 1984; Clark *et al*, 1985). Abdominal-diaphragmatic breathing is enhanced by relaxation, but suppressed

by conditions of emotional strain (Faulkner, 1941); in view of the effect respiratory function can have on other physiological systems, especially cardiovascular function (Grossman, 1983), some training in breathing exercises or control is therefore strongly indicated for anxiety control techniques.

Recently, the move towards psychological treatment of anxiety has been boosted by the increasing recognition of dependence problems associated with benzodiazepines (Ashton, 1984; Lader, 1983; Tyrer *et al.*, 1983) and of the fact that they do not increase the efficacy of behavioural treatments (Grey *et al.*, 1981; Sartory, 1983). This has been especially true in primary care (e.g. Teare Skinner, 1984). The use of such methods as relaxation training by different professions, often simply by handing out taped instructions, has generally increased, and such taped instructions and booklets are now widely available. However, little is known about the effectiveness of such modes of presentation.

The present study was performed to examine a number of questions:

- Would applied relaxation training (ART) be efficacious in generalised anxiety?
- Could ART be taught in a single session and be learnt through home practice?
- Would the mode of instruction differentially affect efficacy?
- Would different types of symptoms be differentially affected?
- If efficacious, could a non-specific effect be responsible for improvement?
- What factors are important in predicting improvement?

Method

Subjects

Fifty consecutive referrals to a district psychology department were randomly allocated to one of four treatment conditions or to a waiting list control group; patients had been referred either from the Department of Psychiatry or directly from general practitioners.

Patients were included in the study if their main presenting problem and referred problem was that of generalised anxiety. This was defined as:

- experiencing panic attacks that were not situationally determined
- experiencing high levels of general anxiety and tension, and complaining of an inability to relax most of the time
- physical symptoms of anxiety being present and a major source of complaint.

Many patients also complained of other problems such as situational anxiety (e.g. agoraphobia) and mild-to-moderate depression; those whose principal complaint was

of situational anxiety or who were at risk of suicide were excluded. Many patients were on psychotropic drugs, but those who thought their medication was no longer producing any improvement were included, and were asked to continue taking their medication. Details of the characteristics of the sample are presented in Table I.

Dependent variables

Self-report instruments. At pre-treatment and post-treatment assessment, patients completed the Symptom Rating Test (SRT) (Kellner & Sheffield, 1969; 1973) and the Epstein-Fenz Anxiety Scale (EFAS) (Fenz & Epstein, 1965; Fenz, 1967). The SRT consists of 30 items, each rated on a four point scale, and provides both a total score and four sub-scales: anxiety depression, somatic symptoms and inadequacy. It is designed to measure distress, and has been shown to discriminate between neurotic and normal subjects, and to change in the expected direction in neurotic patients after treatment (Sheffield & Kellner, 1970). The EFAS consists of 43 items, mostly from the Taylor Manifest Anxiety Scale, each rated on a five point scale. The sub-scales relate to autonomic anxiety, striated muscle tension, and feelings of fear and insecurity. All three sub-scales have been shown to differentiate between normal subjects and psychiatric patients 'diagnosed as anxiety neurotics' (Fenz, 1967).

Benefit gained. At post-treatment assessment, the subjective benefit of treatment was assessed on a three point scale

TABLE I
Sample characteristics

No. of subjects	50
Proportion of females	60%
Mean age: years	40.5 (s.d. 10.8)
Mean duration of symptomatology: years	5.34 (s.d. 5.92)
Marital status	
Single	10%
Married	74%
Other	16%
Unemployed	44%
Source of referral	
Psychiatrist	84%
GP	14%
Self-referral	2%
Taking hypnotics	14%
Taking minor tranquillisers	46%
Taking antidepressants	28%
Taking neuroleptics	4%
Previous psychiatric history	42%
Previous treatment	
None	32%
GP ¹	26%
Psychiatrist	42%

1. Patients who had received psychotropic medication from their general practitioner

(0 = none or minimal benefit, 1 = beneficial, 2 = very beneficial). The patient was asked what effect the treatment had had on his anxiety problem; a rating of 2 was only given if the patient responded spontaneously that the treatment had been very beneficial.

Further treatment. A number of patients needed further treatment, and it was considered unethical to withhold this from patients so that follow-up data could be collected. However, such data from patients not requiring further treatment would be impossible to interpret, due to the sample being highly biased. A measure of further treatment required was used instead, the scale being 0 = further treatment not required; 1 = further instructions on relaxation methods needed only; 2 = further treatment besides relaxation required. Once patients were discharged, they were advised to contact the department if they needed to; classification was made at post-treatment, or if they contacted the department during a minimum 6 months post-discharge period. Since some patients required other treatments for multiple problems, e.g. exposure for situational anxiety, this measure of improvement is conservative.

Subjective compliance. Patients were instructed to practise their exercises at least once a day. If they felt these were helpful, or if they were troubled either by a panic attack or by high levels of tension, then they could practise more frequently. Patients were asked to keep a record, on a provided record sheet, of every time they practised the full exercise procedure, and to estimate their anxiety levels before and after on a scale of 0–100. They were told that the purpose of the record keeping was to see if their anxiety levels decreased after the exercises. Compliance of 100% would be achieved if the exercise routine was practised once a day, and practice in excess of this would be regarded as a behavioural index of perceived usefulness of the exercises.

Procedure

Patients were randomly allocated to one of four treatment groups or to a waiting list control; those in each of the treatment groups were consecutively allocated to either an expectancy or counter-expectancy condition (see below). Patients in the waiting list control group were sent an appointment for approximately six weeks ahead, together with the SRT and EFAS and instructions to complete these (indicating how they had felt over the past week) and to return them in the envelope provided. Assessment of suitability was made both from the referral letter and at interview. Patients in the four ART treatment groups were interviewed, and recruited if suitable for study. They then completed the SRT and EFAS; a further appointment was given for one week later.

Treatment groups

The four ART treatment groups were each instructed by a different method: (a) handout (written instructions); (b) tape (taped instructions); (c) participant demonstration

(verbal instruction and practice); and (d) combined methods (written and taped instructions to take home, with verbal instruction and practice during the session).

All patients received a rationale for applied relaxation training, which emphasised the ability to control physical symptoms through the use of correct breathing and tension release exercises, and the use of imagery to distract attention from anxiety-associated cognitions.

The ART method has the following components: (a) self-monitoring of anxiety levels; (b) correct breathing—monitoring of breathing and the use of exercises to encourage diaphragmatic breathing; (c) progressive muscle relaxation, consisting of tension release exercises; (d) positive mental imagery.

In each of the treatment groups the content of the material was the same but the mode of presentation differed. After the basic rationale, the Handout group received written instructions on the ART exercise routine. Patients in the Tape group were given taped instructions only. Patients in the Participant Demonstration group were given a demonstration of the ART exercise routine in which they participated by following the instructions and model of the therapist. The Combined Treatment Group received the live instruction during the therapy session, as had the Participant Demonstration Group, and were also given written instructions and a tape as in the other two groups.

Expectancy conditions

The ten patients in each treatment group were alternately allocated to either an expectancy or counter-expectancy group. Patients in the former group were told that they should expect continued benefit every time they fully practised the exercise routine, which would increase the more they practised. This point was strongly emphasised. Patients in the counter-expectancy group were told that benefit was slow to become apparent, and that they should not expect to feel any benefits from the exercise routine before the next appointment (post-treatment assessment); they should, however, practise as instructed. Again, these points were strongly emphasised. The counter-expectancy condition was designed to reduce the non-specific effects of the expectancy of improvement from receiving treatment.

Patients were given a further appointment for approximately five weeks later, during which the post-treatment assessment took place. Four patients failed to attend for this assessment (two from the Handout group and two from the Combined Treatment group).

Statistical analysis

Results were analysed using a standard statistical package. Results are presented in terms of percentages or of means and standard deviations. Bivariate comparisons are presented in terms of analysis of variance, while outcome is described in terms of analysis of variance of paired *t*-tests. Correlation coefficients (*r*) between variables are also presented. Attempts were made to incorporate multiple regression techniques in the prediction of the various outcome measures. To do this, the ϵ^2 coefficient was calculated; this can be interpreted as the proportion of the total

variability in the dependent variable that can be accounted for by knowing the value of the independent variable (Nie *et al.*, 1980).

Results

Success of the experimental design

There were no differences across the groups in age, marital or employment status, duration of symptomatology, source of referral, or medication usage (whether minor tranquilisers, antidepressants, hypnotics, or neuroleptics). By chance, there were no males in the demonstration group, leading to a gender imbalance, but since there was no gender difference on any of the outcome measures this did not seem to merit further consideration. As would be expected, the average time of treatment sessions was less for the Handout and Tape groups than for the Demonstration and Combined groups.

There was no difference on initial psychometric scores between the expectancy conditions, demonstrating that random allocation had been successful. At outcome, the counter-expectancy group showed a trend towards high SRT total scores, ($\epsilon^2 = 9.9\%$, $P < 0.07$) and SRT depression subscale scores ($\epsilon^2 = 10.7\%$, $P < 0.06$). A clear difference was evident on the SRT anxiety sub-scale ($\epsilon^2 = 13.9\%$, $P < 0.03$). No difference was evident on the other scales.

Association between variables

There was a significant negative correlation between the psychologist's assessment of further treatment need and the patient's self-rating of perceived benefit ($r = -0.6$, $P < 0.001$). A complete association between the two measures would not be expected, since although a patient may perceive benefit for his generalised anxiety he may still need treatment for other problems such as situational anxiety or depression. There are also significant positive correlations between further treatment need and SRT (total score) ($r = +0.33$, $P < 0.05$), SRT (anxiety) ($r = +0.43$, $P < 0.05$) and insecurity ($r = +0.38$, $P < 0.05$) at post-test. There were no significant correlations with pre-test measures. There were significant negative correlations between perceived benefit and SRT (total score) ($r = -0.38$, $P < 0.05$), SRT (anxiety) ($r = -0.42$, $P < 0.01$), SRT (depression) ($r = -0.37$, $P < 0.05$), and SRT (inadequacy) ($r = -0.39$, $P < 0.02$). There were no significant correlations with pre-test measures: this indicates a high agreement between the psychologist and patient on improvement. The agreement between the interview ratings and the standardised self-rating tests is significant, but fails to explain a considerable amount of the variance.

Outcome of study

Perceived benefit. Approximately 70% of the treated groups reported at least some benefit. The difference among the four treatment groups was minimal ($\epsilon^2 = 2.0\%$, NS) (Table II).

Further treatment needs. The therapist considered that about 60% of subjects were in need of further treatment;

differences among the treated groups were not significant ($\epsilon^2 = 7.4\%$, NS) (Table II).

Self-reported compliance. One third of the group had complied with the instructions on 14 days or less; about 25% practised on 29 days or more. The mean number of days practice was 23.1 (s.d. 15.7). There were no significant differences between treatment groups. Compliance was also calculated as the percentage of times practised, where once per day would indicate 100% compliance; 24% of patients had a compliance of 76% or more, and there was a mean compliance of 68% s.d. 42.0, range 0–200%. There were no significant differences between groups ($\epsilon^2 = 4.9\%$, NS). Compliance was significantly correlated to perceived benefit ($r = +0.68$, $P < 0.001$) and significantly negatively correlated to further treatment need ($r = -0.40$, $P < 0.02$).

Psychometric scores. No differences were found between the pre-treatment psychometric scores for the different treatment groups, confirming that random allocation had not by chance produced any pre-treatment psychometric differences. Results for all patients are given in Table III. Significant differences were found between pre-treatment and post-treatment on SRT (total score), SRT (somatic), and the three EFAS subscales and approached significance on SRT (anxiety). No differences were found in the Waiting List group.

Some psychometric differences among the treatment groups are evident. The Handout group showed a reduction only in autonomic anxiety ($t = 2.61$, $P < 0.05$). The only clear difference evident in the Tape group was a reduction in insecurity ($t = 2.29$, $P < 0.05$), although non-significant trends were noted in SRT (total) ($t = 2.00$), SRT (anxiety) ($t = 2.06$), SRT (somatic) ($t = 2.15$), and autonomic anxiety ($t = 2.05$). The Participant Demonstration group showed a significant reduction in autonomic anxiety ($t = 2.37$, $P < 0.05$), as did the Combined group ($t = 3.27$, $P < 0.02$); the latter group also showed a significant reduction in insecurity ($t = 2.08$, $P < 0.05$).

Expectancy. There were no significant differences between the expectancy conditions on any of the four major treatment variables, so that it was unnecessary to consider expectancy as a covariate in the rest of the analyses.

1. P not significant for any scale

Conclusion

In general, treatment groups improved significantly more than the Waiting List control group, but there were few differences among the different types of treatment. Random allocation to experimental and control groups proved successful. The initial demographic and clinical variables were unrelated to outcome, but initial psychometric scores, unsurprisingly, were highly correlated with final levels. Manipulation of the expectancy condition was influential in terms of differences on some of the psychometric measures at outcome, but showed no relationship with perceived benefit, further treatment need, or the two measures of compliance.

Discussion

The results will initially be discussed in terms of the questions previously formulated.

(a) The results indicate that ART does produce short-term improvements in patients with generalised anxiety, compared with a waiting list control group (who showed no improvement).

(b) It does appear to be possible to teach a therapeutically effective self-help skill in a single session followed by home practice. Approximately 70% of patients reported having received some benefit from the single session and home practice, and nearly 20% reported receiving great benefit. However, approximately 60% required some form of further intervention. Although reported compliance with home practice was extremely variable, it appeared to be associated both with the patients' and the psychologist's assessment of improvement; however,

correlations do not allow an interpretation of the direction of this relationship. This subjective rate of compliance is approximately equal to the 71% found by Barr Taylor *et al* (1983) with hypertensive patients.

(c) The type of instruction given did not significantly effect outcome. There was no consistent superiority in any of these four methods of presentation.

(d) Measures that reflected the physical and somatic aspects of anxiety, e.g. the SRT anxiety and somatic scales and the EFAS, responded best to treatment. There was no significant improvement in the SRT inadequacy scale, which represents a more cognitive dimension of anxiety, and no evidence that ART had any effect on depression. Hence there is a differential treatment effect on types of symptoms, reflecting an improvement in physical and somatic symptoms, but with little generalisation to cognitive and mood-related symptoms. This is also reflected when the four treatment groups are examined separately. Surprisingly, the muscle tension scale did not show significant improvement. It would have been expected that a treatment method that included progressive muscle relaxation would have an effect on reports of striated muscle tension, but this was not demonstrated.

(e) There was evidence of a non-specific effect in treatment: two scales of the SRT showed a significant difference, and two other scales approached significance. The results indicated a better outcome for patients who had an expectancy of improvement with practice. These differences were not related to

any of the treatment groups, and can therefore be thought of as a generalised expectancy effect. However, expectancy of improvement was not related to subjective estimates of benefit, nor to the psychologist's estimate of further treatment needed. Nor was there a relationship between expectancy and compliance, so the effect of expectancy was not mediated by amount of practice. The evidence suggests that non-specific effects manipulated by the therapist do contribute to treatment outcome, but that not all improvement can be explained solely by expectancy manipulation.

(f) Attempts to identify predictors of improvement were unsuccessful. It was interesting that different types of psychotropic medication did not affect outcome.

This was a clinical trial of a method of anxiety reduction. The subjects, 42% of whom had a previous psychiatric history, included patients who had experienced symptoms for long periods (mean 5.34 years, s.d. 5.92, range 2.4 months to 18 years). Only 30% of those who received ART were not taking psychotropic medication. Although this population included many patients with a chronic anxiety problem who were not improving on other treatment regimes, one session during which instruction in ART was given produced small but significant improvements. Of these patients, 39% needed no further treatment, and a further 17% needed only further instruction in relaxation. Although 44% needed further behavioural treatment, some had also presented with other clinical problems.

In a trial of AMT with a similar clinical population of generalised anxiety patients, Jannoun *et al* (1982)

demonstrated the superiority of AMT over a no-treatment waiting list period; their treatment method can be thought of as most comparable to the combined treatment group in the present study, although their patients received further instruction in relaxation as part of the procedure. The results of the present study support those of Jannoun *et al* in demonstrating the usefulness of anxiety management-type techniques in generalised anxiety. No evidence was found in the present study to demonstrate a consistent reduction in depression.

In contrast to previous studies on relaxation (Borkovec & Sides, 1979; Hillenberg & Collins, 1982), we found no advantage in live presentation of relaxation methods during the treatment session. This may be due to the fact that only one treatment session was given; if treatment had been extended over a number of sessions it is possible such differences would have become apparent. However, since there is no advantage in a single session live participant demonstration, giving taped or written instructions may be desirable, due to a significant economy of time. If patients do not improve, then more intensive efforts can be employed. The fact that the patient's expectancy of improvement—manipulated by the therapist—can affect outcome signifies the importance of presentation of the treatment rationale, and the method employed is probably crucial.

Acknowledgement

The authors would like to thank the patients who participated in the study and Miss Linda Rainford for patiently typing the manuscript.

Disturbance of Water and Sodium in a Manic-Depressive Illness

J. L. CRAMMER

Specific questioning and frequent observation of a 69 year-old woman with cyclic bipolar manic-depressive illness showed that she had disturbances of thirst, appetite, bowel and bladder function and dramatic changes in body weight, in association with different phases of her mental illness. Examination of one manic phase under constant diet and inpatient control showed cardiovascular changes, sodium retention, body weight gain, with raised aldosterone secretion but steady vasopressin. There appears to be a sub-group of manic-depressive patients with evidence of disturbed hypothalamic functions as part of their mental illness, as shown particularly by changes in water and electrolyte metabolism.

Recent interest in the possible role of vasopressin in affective illness (Gold *et al.*, 1984) revives the need to examine water and electrolyte metabolism in manic-depressive patients.

The following case was selected for longitudinal study because in an earlier brief hospital admission her weight had suddenly risen in a few days by 3 Kg. during a manic attack, although this rise had been ascribed at that time to the drug therapy. The first study followed her through one manic-depressive cycle to confirm that her fluid balance varied with mental state independently of any drugs; the second examined a later manic attack in more detail under controlled conditions, to establish the nature of the disturbance in water and electrolyte metabolism.

The case

A former physiotherapist married to a doctor who was a keen clinical observer began at age 54 to have recurrent cycles of manic-depressive disorder lasting 45-70 days, as a consequence of which she had numerous hospital admissions and treatments, including ECT for the depressive phase on a number of occasions, and trimipramine, chlorpromazine, lithium carbonate and other drugs. At the times of study this illness had been running for 15-16 years.

The family history was positive: her father and his brother had both suffered recurrent depressions, and their father was said to have been a manic-depressive. The patient's younger sister suffered depressions following the menopause.

The patient herself had had episodes of "losing grip" lasting a week or two at ages 17 and 22, episodes of depression and tearfulness at ages 37, 38 and (puerperally) at 40.

On the physical side she had had appendicectomy at 26, left mastectomy for carcinoma at 54 and cholecystectomy (many small stones) the following year.

Description of the attacks (from husband and patient)

The cycles began with 5-7 days of gastric disturbance, flatulence, occasional epigastric pain, and loose stools. She became uncommunicative, began to feel depressed in mood, slowed down in thought and movement, had difficulty making up her mind, could not remember how to perform simple kitchen tasks or even to wash herself. These depressive phases slowly waxed and waned over about 3-4 weeks.

They were followed at once by hypomanic phases, each heralded by a sudden desire, continuing for two weeks, to eat chocolate or honey. She became constipated, was awake and active all night or at least until 3 a.m., became thirsty (up to 3 L. per day) and developed some urinary urgency and occasional incontinence. She was busy, talkative, sociable, unpredictable, an overspender, generous, broke things easily, was emotional, sexually alive, and felt happy. This phase waxed and waned over 3 weeks and was then followed by about three weeks of normality before the mood cycle started round again: cycle length about 70 days, noted, when in hospital, from age 62 at latest.

Study I

The patient was admitted for observation over seven weeks of a complete mood cycle. She was just two weeks into a depressive episode, with slowed movement and laboured speech, monotonous and without spontaneity, mostly about the hopelessness of her condition. She had been taking lithium carbonate ('Priadel') 1200 mg each night, and diazepam 5 mg at night and thrice daily for a long time, and it was decided to hold these constant through the whole admission rather than complicate the phenomena in the limited available time by introducing a withdrawal and wash-out period. The plasma lithium at 9 a.m. on many occasions from April 1 until mid-May was always 1.0 or 1.1 mmol/L., but on May 13 was 0.9, on May 15 0.6 mmol/L. (hypomanic phase ending, weight dropping) then returned to the 1.0 level, rising on June 3-20 to 1.5 mmol/L. at a time of great weight loss, before settling again to 1.0 mmol/L.

No attempt was made to control the patient's food intake, except that she ate only the official ward meals provided. Her fluid intake was measured as far as possible, and her urine was collected as a series of 24-hour specimens, which were analysed for creatinine (and for Na, K, Ca, Mg) by autoanalyser or absorption spectrometry. Daily urinary creatinine measurement is often a rough constant at about 20 mg/kg body-weight of a patient, and in this woman (weight about 56 kg) was very often 0.9–1.1 g per day, but at other times between 0.7 and 1.4 g due either to errors in timing consecutive urine specimens or to fluctuations in renal blood flow.

During the manic phase urine samples were taken on several occasions for aldosterone and vasopressin radioimmunoassay, very kindly carried out by Dr. J. D. H. Slater and his colleagues at the Middlesex Hospital (Jowett *et al.* 1973).

Plasma samples were taken at intervals for packed cell volume by carefully standardised haematocrit, as a measure of blood hydration, and for plasma Na and K and serum albumin by standard methods.

The patient was weighed daily before 8 a.m. in her night-dress, standardised as described by Crammer (1957, 1983).

Results

Figure 1 shows a depressive episode which began March 14 and ended about April 21, or after five weeks. The hypomanic phase began May 1, and ended about May 14 (two weeks), to be followed by a slow onset of depression from about May 22. Thus the complete cycle appeared to be March 14 to May 22, or 69 days long, which agreed with previous reports in this patient. The daily body weight was far from steady (unlike that of a normal person) and showed at least four changes greater than the maximum gain per day (250 g) expected from forced feeding, or maximum loss per day (500 g) from complete starvation without extra sweating (Crammer, 1983):

- Phase 1: April 9–17, weight rises from 53 to 57 kg, or average 500 g per day while depression lessens: fluid retention.
- Phase 2: April 18–20, weight falls 57 to 55 kg, a loss of 1.5 kg in two days: fluid loss.
- Phase 3: May 2–15 weight rises steadily 54.5 kg to 59 kg, 350 g per day: fluid retention. While hypomanic, this was accompanied by complaint of thirst, high fluid intake, and a 24-hour urine output of 5 litres.
- Phase 4: May 15–24, weight falls 59 to 56.5 kg then levels off at 57 kg for a week.
- Phase 5: May 29 to June 1, fall from 57 to 54 kg at a time of mounting depression.

Weight gain due to fluid retention is accompanied usually by sodium retention (maintaining osmolarity), and weight loss due to extracellular fluid loss is accompanied by a loss of sodium in urine. Table I shows the results of daily urine analyses in the different phases, with mean daily excretion in each phase. The values must be considered with caution, since food intake, which was not regulated, can alter these values. However the main

FIG 1 Changes in body weight, urinary sodium and calcium, and in plasma haematocrit (packed cell volume) and sodium between 2 April and 21 June (Study I). Below the dashed line at the top representing days is an indication of mood state, shaded areas below the horizontal line representing depressive episodes, clear enclosed area above manic phase. Note particularly that while body weight rises constantly during manic phase (phases 3–4), daily urinary sodium loss shows two stages, marked at first, but with a very striking drop during the last 5 days of the manic phase suggesting marked sodium retention at this time.

changes are consistent within the phases and the results are suggestive.

When weight fell in phases 4 and 5 the daily urine loss of sodium was of the order of 160–180 mmol, when weight rose in phase 1 the loss was only 80 mmol. If dietary sodium was about 150 mmol per day, these are the urine values to be expected with the recorded weight changes. In phase 3, however, the situation was more complex, with a big weight gain yet a daily sodium loss of nearly 140 mmol, about the same as in the weight loss of phase 2. However at this time the patient complained of thirst and certainly

See text for discussion of values

drank more: Table II shows urine output of 4.0 to 5.4L during manic phase in May, but only 1.5 to 2.5L in the following depression. She may have eaten more too because the potassium excretion rose to a daily 67 mmol on average, certainly at its highest in this phase, yet the Na:K ratio remained steady through phases 1, 2, 3 at 1.8, 2.1, 2.0 respectively (but rose to 3.2 during the sodium and weight loss of phase 4).

The complexity of the manic phase was further emphasised by the plasma measurements (bottom of Fig. 1). In spite of thirst and climbing body weight the plasma sodium was about 137 mmol/L, having fallen from 146 mmol/L in depression and climbing back to that value about May 28 as depression reappeared. The packed cell volume also fell to its lowest as manic phase ended. In other words during phase 3 the plasma was more hydrated, the osmotically active sodium lower than at any other time, yet this was the time of thirst and greater fluid intake. One explanation could be a small inappropriate secretion of antidiuretic hormone at this time, and the incomplete figures available for Table II show the urine osmolality low yet the antidiuretic hormone well maintained. During the depressive phases, when the plasma sodium was higher, and water formed a smaller fraction of whole blood, the patient experienced no thirst. It was necessary to re-examine these phenomena under better control in a later manic phase.

Study II

The purpose was to re-examine the manic phase (phase 3) under better controlled conditions, and confirm the findings

The patient was re-admitted the following January towards the end of a depressive phase and placed on a constant diet of known composition for 16 days. The first five were settling-in days: manic phase began on the sixth day (January 18). Mineral and fluid balance, with some relevant hormonal measurements, and clinical observation of mental state, body temperature, blood pressure, etc. were carried out daily, essentially as before. Since Study I her husband had noted three manic phases, each associated with restless nights, marked thirst, a degree of urinary

incontinence, and a weight gain (on bathroom scales) of about 6 kg

Diet

A dietician (Miss P. T. Carden) from the nearby general hospital (King's) very kindly prepared a diet adequate in calories and liked by the patient, in which *the same quantities of the same foods were eaten each day*, and the daily mineral intake calculated with the help of tables (McCance and Widdowson 1960). The diet allowed 50 g salt-free bread, 30 g salt-free butter, 400 g milk, 100 g orange squash, and otherwise distilled water, 40 g lamb and 30 g chicken breast, oatmeal, 50 g potato, and other vegetables and tinned fruit, jelly, Nescafe, and so on, to give a varied menu in the 24 hours. Care was taken to cut all meat from the same joint, and to use a single baking of bread, etc., to aim for uniformity of analysis. The calculated mineral intake was sodium 34 mM, potassium 56 mM, calcium 19.4 mM and magnesium 4 mM. The 24-hour urine content of these ions on the fourth and fifth pre-manic days, which may be taken as the basal starting state, was Na 36, K 42, Ca 1.13 and Mg 1.8 mM: since it is known that in man virtually all the day's sodium intake and four-fifths of the potassium are normally excreted in the 24-hour urine, these values agree well with the calculated values for the diet. It had been intended to have a higher daily sodium intake than this by supplementing with a known weight of oral sodium chloride, but this was omitted in error. However, the results are still interpretable, although the effect was probably to reduce the degree of sodium retention and of weight gain (as in another patient, Crammer 1959b).

Fluid intake was free, but always measured, and in fact was roughly constant at 1.5–1.75 litres daily, until with the onset of thirst on the seventh manic day it rose above 2.0 L. (see Fig. 2). The patient had her own bedroom, stayed in the ward under nursing supervision the whole time, and only had access to water and toilet facilities under observation. All urine was collected as a sequence of 24-hour urine specimens. She continued to receive her

FIG. 2 End of depression, start of manic phase indicated by vertical dotted line. Constantly daily sodium intake 13–28 January, indicated by the dark horizontal line: the shaded rectangle indicates the four days when lithium doses were omitted.

Water intake shown by the top of each plain rectangle, urine output by the bottom: where this is below baseline there is net fluid loss, where above baseline net fluid retention (from January 24).

Sodium excretion is steady for four days, and retention (below horizontal dotted line) begins on January 20.

Aldosterone (dashes in lowest figure) rises anew from January 21 to January 24; vasopressin (continuous) fairly level January 12–28.

usual drugs, nitrazepam 5 mg at night, and 800 mg lithium carbonate (Priadel) every morning, except on the four days shown below.

Blood pressure

At 09.30 each day she had always been lying supine for at least 30 minutes, when I took her pulse and blood pressure,

and a blood sample. She then got up, walked about for half an hour, and then sat down, erect, for a repeat of pulse, blood pressure and venesection.

Laboratory

Na, K, Ca, Mg were measured by atomic absorption spectrometry; creatinine, and plasma concentrations of urea, urate, albumin, bilirubin, cholesterol, phosphate and chloride by autoanalyser; packed cell volume by haematocrit; plasma osmolality by freezing point determination; aldosterone, antidiuretic hormone, and plasma renin were kindly measured by Dr J. D. P. Slater and his staff at the Middlesex Hospital.

Results

(a) *Clinical*: On first four days (January 9–12), she was at first slowed, with inability to concentrate, concerned about her bowels, slightly nauseated, not thirsty, but improving to the end of this period. On January 13 she started her special diet, and continued to develop some spontaneity; on January 15 and 16 she was free of depression, more active and normal. Normal stools were passed on January 11 (126 g) and 12 (176 g) and also on January 15. A further stool was passed on the night of January 16, and two further stools on January 17, and these last three were all much softer and came with some urgency. Thereafter she was constipated, with small stools on January 20 and January 28 only.

On January 18, the manic phase began, but at first it was extremely mild. However, by January 22 she was sleeping less (drop from 8 to 5 hours), had become talkative, with some urge to speak, and not always to the point. By January 25 she was very talkative, thoughtless, restless, and joyful, and was complaining somewhat of thirst, as in previous cycles. She longed to smoke a pipe, and eat chocolate.

(b) *Cardiovascular*: The resting pulse was very steady from day to day at 47.6 per min average on the five pre-manic days, and 50 per min from January 18–29 (manic phase) (Table III). But when the effect of exercise and posture was examined there was a striking difference between pre-manic and manic. In the first (six) days the pulse was always quickened after exercise by 3–9 beats/min, but on January 18 and thereafter it was always slowed by a similar amount, an abnormal response.

Blood pressure showed a 27% increase in resting diastolic pressure with onset of manic phase (see Table III), with a much smaller rise in systolic pressure. As expected, both pressures increased on exercise and change of posture, to about the same extent in pre-manic as in manic phases (normal). The changes in pulse and diastolic pressure occurred at the very start of hypomanic phase, long before there was a noticeable increase in physical activity. They were consistent with the idea that there was a change in central vasomotor control from the start of manic phase, resulting in a change in renal blood flow and an increased sodium retention.

(c) *Sodium and water balance*: Figure 2 and Table IV show what happened. There was little change over baseline until the third manic day (January 20) when sodium began to be

retained, and this continued for the remaining metabolic days. Water only began to be retained on the seventh day (January 24). The weight gain over 5 days (January 24–29) was only 1.3 kg, the total sodium retention by the 29th of the order of 160 mM, which at an extracellular fluid concentration of 140 mM/L is worth a weight gain of nearly 1.2 kg. The positive fluid balance over the last five days implies retention of about 1.5 L. These values agree quite well. In the hypnomanic phase of Study I, and in the husband's reports they were three times bigger. Here they are probably small because of the rather low sodium in the diet. In an earlier case (Crammer, 1959b) varying the daily sodium intake altered the sodium and water retention.

If we look at plasma changes (Table V) the haematocrit dropped with the onset of manic phase, 42% to 39%, a smaller change than noted in Study I, but again pointing to increased hydration of the blood. Plasma sodium showed a tendency again to fall, most noticeable in the last five days, the plasma osmolality likewise, and the plasma albumin and urea also fell in the last four or five days. This was a time when clinically thirst was most in evidence and a higher plasma osmolality would have been expected.

In a short-cycle manic-depressive previously studied (Crammer, 1959b) while off all drugs, phases of sodium and water retention were observed in step with the mental states, with fall in resting pulse, rise in body weight, and in particular the same fall in PCV and plasma sodium and evidence of increased hydration of the blood as noted here. Jenner *et al.* (1967) also noticed such a change in their case.

Antidiuretic hormone (Fig. 2 and Table V) fell steadily as osmolality fell, and therefore could not be seen to be playing any part in the fluid retention and thirst of January 24 and after. Paradoxically, at the end of the depression (Phases A and B), plasma osmolality and sodium were quite high (higher than in Study I) but there was no thirst, antidiuretic hormone was not greatly raised, and in fact sodium and water excretion were up, and the body weight falling. There is no evidence here of a role for arginine vasopressin in the pathophysiology of this illness (compare Gold *et al.*, 1984). If antidiuretic hormone can come into play it may do so following a much greater degree of sodium retention.

The salt retention took priority in this patient's manic phase, and her aldosterone rose at this time, although already at a high steady level because of the rather low daily sodium intake. No increase in potassium excretion was seen, however. Aldosterone was not raised in Study I, perhaps because dietary sodium was freely available. Plasma renin activity did not show any relevant change. It was higher while the controlled low sodium diet was given, but did not rise in the manic phase, and the effect of posture and exercise remained similar in non-manic and manic conditions.

(d) *Calcium and magnesium*: Urinary magnesium increased in the manic phase, starting on the fourth day (January 21), a change from about 1.75 to 2.10 mM per day, a 20% rise. Calcium remained roughly constant, with a 10% drop only in the last four days, and plasma calcium was constant until this time and then fell slightly.

Note the raised magnesium, lithium and calcium on the switch day (Jan. 18)

Thus, the suggestion from Study I of increased urinary magnesium loss in manic phase was confirmed by the metabolic balance study. The onset of manic phase on January 18 was marked by looser stools, before constipation set in, and by high excretions of magnesium and lithium, and to a lesser extent of calcium, just for 24 hours.

The significance of these changes is uncertain: it would be necessary to confirm their re-occurrence at each manic onset, or in other similar patients, and to examine changes in fecal minerals at the same time to begin to analyse what may be coincidence, an effect of physical exercise, or of changed bowel habit or altered renal function, or have some other explanation.

Discussion

Physical signs and biochemical disturbances in the course of a major psychiatric illness may be purely coincidental, perhaps due to some concomitant physical illness, or quite commonly result from a change in the patient's behaviour (Kety, 1959). In spite of many years of hope and study (Barnes & Francis, 1909; Pighini, 1907; Gjessing, 1976), no

biochemical disturbance has been found causal of a major psychosis. There is, however, another but neglected possibility, that changes in the regulation of the body temperature (Nikitopoulou & Crammer, 1976), of pulse and blood pressure, or of urinary secretion may be signs of central nervous disturbance quite as much as are the appearance of hallucinations or of pathological mood.

In the present case, long-standing undoubted bipolar affective disorder has been shown to be accompanied by pathological variations in body weight, due in part to changes in the renal excretion of sodium and in the retention of water, and accompanied by pathological thirst in the manic phase. This phase has also exhibited a change in cardiovascular regulation. These phenomena were all small, and easily overlooked. They have on occasion been reported in other patients before (Klein & Nunn, 1945; von Stockert, 1958; Crammer, 1959b; Jenner *et al*, 1967; Hullin *et al*, 1967, 1977; Allsopp *et al*, 1972), mostly in cases who were drug-free. It

seems evident that in some, though perhaps only in a minority, functional psychoses may have physical signs and biochemical signs just like other illnesses. It is least difficult to detect them in repeating periodic illnesses (Crammer, 1959a; Jenner, 1968) but there is no reason to suppose they will be confined to such illness and they need to be sought much more often. We accept the idea that hormonal provocation tests such as the dexamethasone suppression test (Carroll, 1982) or the clonidine-growth hormone test (Checkley *et al*, 1981) may help in diagnostic differentiation, in exploring central nervous dysfunction, and in predicting success in pharmacotherapy. Should we not similarly take advantage for the same purposes of the disturbances in regulation of water and electrolytes which occur naturally in the course of psychiatric illness? They are easy to follow clinically in terms of weighing the patients - and collecting timed blood and urine specimens for simple analyses. Psychiatric diagnoses are based on the grouping of symptoms, and a label such as catatonic schizophrenia or major bipolar affective disorder carries no guarantee of pathophysiological unity. On the other hand cases which have in common a disturbance in cardiovascular

regulation, or in body weight may be found to have also a similarity in pharmacological response.

The observations here concentrated on the manic phases. In Study I on free food and water, weight gain appeared as a consequence of thirst and water retention; the blood becoming increasingly hydrated. Some pilot data suggested that vasopressin secretion, (Gold *et al*, 1984) might be playing a role, while aldosterone appeared unimportant. In Study II, which examined the manic onset rather than the manic ending, and which severely limited daily sodium intake, the reverse seemed to be true. Sodium retention came first, before there was any thirst or increase in water intake or in weight, and it seemed possible that aldosterone was involved rather than vasopressin. Hullin's group (Allsopp *et al*, 1972; Hullin *et al*, 1977) have been pioneers in emphasising the importance of aldosterone in these cases. One might speculatively develop a hypothesis that the manic phase may begin with a vascular disturbance, particularly renal and leading to inappropriate aldosterone secretion and sodium retention. At a certain point, the sodium input stimulates thirst and vasopressin secretion, and the resulting dilution of sodium results in a cut-off of thirst and of manic

symptoms and return to the starting point. Thus the manic phase would have different mechanisms predominating at different times in its course.

However this may be, modern renal physiology emphasises the angiotension-renin-aldosterone system in the genesis of thirst, and a cardiac natriuretic hormone, and nervous control of renal function (Ganong and Barbieri, 1982; Seldin and Gebisch, 1985) as factors also to be taken into account. Elucidation of the mechanisms at work in the fluid disturbances of psychiatric cases will require the application of this knowledge and much better and fuller hormonal measurements than those reported here. The purpose of this paper is to draw attention

to physical signs—cardiovascular, changes in body water, changes in magnesium excretion—which appear to be part of a psychotic illness. Explanation comes later.

Acknowledgements

This work involved very many people. In addition to the patient and her husband and others mentioned in the text (Dr J. D. H. Slater, Miss P. T. Carden), I would above all like to thank Sister C. Gillies, in charge of nursing throughout, and Dr F. W. Fulford, who contributed greatly during his time as registrar. In the clinical laboratory of the hospital, Mr Brian Smith and his colleagues very kindly carried out a number of routine analyses.

(Accepted 2 January 1986)

Panic Attacks: New Approaches to an Old Problem

M. G. GELDER

Anxiety attacks were included in the first descriptions of the syndrome of anxiety neurosis. Recently it has been suggested that such attacks (now usually called panic attacks) characterize a distinct form of anxiety disorder—panic disorder. It has also been proposed that panic attacks result from a biochemical disorder and require pharmacological treatment. Some of the evidence for these ideas is presented, and two other explanations for panic attacks are reviewed: that they are caused by hyperventilation, and that they result from a cognitive disorder. It is concluded that although it is not possible on the present evidence to choose between the three theories, there is strong indirect support for the cognitive theory and good reason to investigate cognitive factors more thoroughly. Future work on biochemical causes of, and pharmacological treatments for panic attacks should take account of such factors.

The syndrome of anxiety neurosis was first described by Freud (1985) in a paper published in a neurological journal under the title "The justification for detaching from neurasthenia a particular syndrome: the anxiety-neurosis." Freud described all the features that we recognise today, and drew attention to one feature in particular: anxiety attacks. Although this was the first description of anxiety neurosis, similar attacks had been noted by da Costa (1871) in his description of 'soldiers' heart'. However, da Costa ascribed the symptoms to a cardiac rather than a nervous disorder—a view shared by many patients today.

A description of panic attacks

Freud's description of the symptoms of an anxiety (or, as it is now usually known, panic) attack is closely similar to that incorporated in the current American diagnostic system, DSM-III (American Psychiatric Association, 1980), under the rubric for Panic Disorder. An attack consists of a rapid onset both of intense symptoms of autonomic arousal and of mental symptoms. Physiological recordings reflect the disturbance, showing increased skin conductance, muscle blood flow, and heart rate (Lader & Mathews, 1970). The mental symptoms were well described by Freud (1895), who drew attention to the interplay of the two kinds of disturbance:

"An anxiety attack may consist of a feeling of anxiety alone, without any associated ideas, or accompanied by the interpretation that is nearest to hand such as ideas of the extinction of life, or a stroke, or the threat of madness . . . or the feeling

of anxiety may have linked to it a disturbance of one or more of the bodily functions—such as respiration, heart action, vasomotor innervation or glandular activity. From this combination the patient picks out in particular now one, now another, factor. He complains of 'spasms of the heart', 'difficulty in breathing', 'outbreaks of sweating' . . . and such like; and in his description, the feeling of anxiety often recedes into the background."

Panic attacks are of two kinds. The first kind are provoked by a stimulus that the patient recognises; in other words, they are a particularly intense form of phobic anxiety. The second kind appears to arise spontaneously; to quote Freud (1895) again, they "erupt into consciousness without being called forth by any train of thought." Nowadays it is generally assumed that the two kinds are equivalent, and they are studied together. However, they could arise in quite different ways, and might respond to different treatments. Indeed, there is a strong clinical impression (though the evidence is still incomplete) that panic attacks which occur in phobic situations and are accompanied by avoidance respond to exposure treatment, while those occurring spontaneously do not but respond instead to imipramine. This account is mainly concerned with the second kind—the apparently spontaneous attacks of panic.

Do panic attacks define a separate disorder?

Freud described panic attacks as a general feature of anxiety neuroses. For many years most psychiatrists shared this view, but it is now commonly suggested

that anxiety neuroses with panic attacks are a separate entity, and this idea is now incorporated in DSM-III. The alternative view—that panic attacks are merely an index of the severity of an anxiety disorder—is still held by many psychiatrists, and it is appropriate to examine briefly the strength of the evidence for the opinion that there is a separate panic disorder.

The idea that panic attacks indicate a distinct form of anxiety disorder was originally proposed by Klein (1964). He based this claim mainly on the observation that panic attacks respond to treatment with imipramine and that the background of generalized anxiety does not. Many of Klein's patients appear to have been agoraphobic, showing avoidance as well as panic attacks; they thus belonged to the first of the two types noted above. Because Klein regards avoidance behaviour as secondary to panic attacks, he has considered it appropriate to combine in his studies patients who avoid (agoraphobics) and those who do not (generalized anxiety neuroses). While this is a tenable position, it is important to be aware of it, because the treatment in the major clinical trial by Klein and his colleagues included both exposure, directed at avoidance, and imipramine, directed at panic (e.g. Zitrin *et al*, 1983). Since there is evidence that exposure alone can reduce the panic attacks of agoraphobic patients (e.g. Hibbert & Chan, 1986) it is necessary, in order to support Klein's position, to show that imipramine alleviates panic attacks in generalised anxiety neurosis. To date this has not been proved beyond doubt, since the evidence published so far is based only on a small group of patients (Garakani *et al*, 1984). However, further evidence on this issue should be available soon from trials now in progress.

Do patients with panic attacks differ from those with generalised anxiety disorder in ways other than their response to treatment? Several authors have reported differences in symptoms. However, these differences are directly related to the symptoms of the panic attacks themselves and are therefore not helpful in answering the question. They include more somatic symptoms (Hibbert, 1985; Hoehn-Saric, 1982; Anderson *et al*, 1984) and more preoccupations with ideas about illness and dying (Hibbert, 1985) among panic attack patients.

Are there any differences not directly due to the panic attacks? The evidence on this point is confounded by the inclusion of agoraphobic patients in the panic attack groups, so that the observed differences may be due, at least in part, to differences between agoraphobia and general anxiety neurosis rather than between panic disorder and general anxiety neurosis. Thus Raskin *et al* (1982) found that

panic attack patients reported more disturbances in their childhood environment, but not difference in loss or separation. They also found that the panic disorder group reported more previous depressive disorders. Crowe *et al* (1983) studied the relatives of probands with panic disorder and found an excess of panic disorder among their first degree relatives, but no increase of generalised anxiety disorder. These family differences suggest the possibility of genetic differences between panic disorder and generalized anxiety disorder, but these differences might only be in the degree of genetic loading, with a greater genetic influence in severe anxiety neuroses than mild ones. It can be concluded that there is as yet no strong evidence that panic attacks mark out a different disorder, rather than a more severe degree of the same one. However, whatever the truth of this issue, the causes of panic attacks still need to be explained.

Causes of panic attacks

The normal responses of fear and anxiety are the final result of a complicated series of physiological and psychological mechanisms. Panic attacks must result from a disorder of some of these mechanisms, and this disorder might be the same in every case, or differ between cases.

A discussion of the causes of panic attacks requires a broad understanding of the mechanisms of anxiety: there are physiological and psychological components, and each has several elements. The physiological mechanisms include control centres in the brain and effector systems in the periphery. The central mechanisms include the locus ceruleus, a nucleus involved in the control of sympathetic activity and in the regulation of arousal. The peripheral physiological mechanisms include autonomic arousal, increased tension in skeletal muscles, enhanced respiration, and the release of adrenaline and noradrenaline.

Peripheral noradrenergic mechanisms

Many of the most obvious symptoms of a panic attack reflect overactivity of the sympathetic nervous system. This overactivity might arise in two ways: from heightened sensitivity of end organs, or from increased activity in sympathetic nerves. The first possibility was suggested by Wearn and Sturgis (1919) who gave intramuscular injections of adrenaline to patients with 'irritable heart' (a condition now generally thought to be identical with severe anxiety disorders). They observed that the same amount of adrenaline produced more symptoms in the anxious patients than in normal controls. This finding might

indicate that anxious patients are unusually sensitive to the effects of adrenaline. However, the differences could be due to variations in absorption from the injection site, and the crucial experiment requires an intravenous infusion of adrenaline. This was done by Fraser & Wilson (1918) and by Hume (1918), and when Wood (1941) combined their results he found that anxiety neurosis patients and controls responded equally.

Since that time, it has been shown that these peripheral sympathetic effects depend on β -adrenergic mechanisms. Nesse *et al* (1984) examined the effect in anxious patients and controls of the specific β -adrenergic agonist, isoproterenol. They found no evidence of increased β -adrenergic receptor responses in panic anxiety patients; indeed, there was an indication that the response was slightly decreased, a finding that could reflect down-regulation of receptors in response to sustained high levels of noradrenaline. Thus although some of the symptoms of panic disorder are undoubtedly related to increased sympathetic activity, this does not seem to be due to hypersensitivity of post-synaptic β -adrenergic receptors.

Central autonomic regulatory mechanisms and panic attacks

The central regulatory mechanisms for anxiety are complicated, but for the purpose of this review they can be simplified by focusing attention on a single important structure: the locus ceruleus, which is situated in the floor of the fourth ventricle. In animals, ascending noradrenergic pathways can be traced from the locus ceruleus to the hippocampus and forebrain, where they probably modulate arousal levels. Descending pathways from the locus ceruleus affect peripheral sympathetic activity.

Three kinds of evidence point to the importance of the locus ceruleus in the regulation of anxiety in animals (Redmond & Huang, 1982). Firstly, stimulation of cells in the locus ceruleus leads to behaviour like that produced by anxiety-provoking stimuli. Secondly, lesions in the locus ceruleus abolish the behavioural response to anxiety-provoking stimuli. Thirdly, the drugs piperoxan and yohimbine, which increase activity in cells of the locus, produce anxiety-like behaviour in animals. Not all the evidence points in the same direction; for example, the drug buspirone increases activity in the locus but reduces anxiety (Sanghera *et al*, 1983).

If a control mechanism of this kind exists in man, panic attacks could arise from excessive stimulation of neurons on the locus ceruleus or from inadequate

inhibitory mechanisms. At present most interest is centred on possible failures of the inhibitory mechanisms. The noradrenergic neurons in the locus ceruleus have receptor sites for several inhibitory neurotransmitters, notably α_2 adrenoceptors, and receptors for gamma-aminobutyric acid (GABA) and encephalins (see Redmond & Huang, 1982). In this review only the α_2 adrenergic autoreceptors will be considered (see Grant *et al*, 1980, for the possible role of GABA-benzodiazepine receptors).

If these poorly-functioning autoreceptors are a cause of panic attacks, yohimbine (a drug which penetrates the blood/brain barrier and inhibits these receptors) should reduce their activity more readily than in generally anxious or normal subjects. Removing an inhibitory mechanism on these cells will increase autonomic activity and arousal. It should also result in a greater increase in plasma 3-methoxy-4-hydroxy-phenylethylene glycol (MHPG), which seems to reflect central noradrenergic turnover.

Charney *et al* (1984) gave yohimbine orally to drug-free anxious patients and to healthy controls. The drug produced greater increases in tremors, palpitations and systolic blood pressure in the patients than in the controls. Anxiety also increased more, and patients reporting the most panic attacks before the test showed the greatest rise in plasma MHPG in response to yohimbine. These findings are consistent with the view that panic attacks develop when there is an abnormal balance between excitation and inhibition at the locus ceruleus (and perhaps other areas of the brain), possibly due to abnormal α_2 receptor function. However, the findings could also be explained if the direct effects of yohimbine are restricted to increases in the physiological symptoms of tremor, pulse rate and blood pressure, while the feelings of panic result from the patient's psychological response to these physical changes. Furthermore, yohimbine is a less selective α_2 adrenoceptor antagonist than certain recently discovered compounds; to be certain that noradrenergic changes are of primary importance this work needs to be repeated with these more specific agents.

Clonidine is another drug that acts on α_2 autoreceptors. Because clonidine is an α_2 agonist it stimulates the autoreceptors, thereby reducing activity in the noradrenergic neurons of the locus. If α_2 receptors are underfunctioning in the patients with panic attacks, clonidine would not be expected to be a powerful way of controlling the attacks. Ko *et al* (1983) gave clonidine to panic attack patients and found only a weak anxiolytic effect, although there were definite effects in lowering blood pressure and producing sedation. These findings are compatible

with the α_2 hypothesis of panic attacks, but certainly cannot be taken as strong evidence for it.

Imipramine and panic attacks

The revival of interest in panic attacks can be traced to the observation by Klein (1964) that imipramine seemed to have a specific effect on this aspect of anxiety disorders. A subsequent clinical trial (Zitrin *et al.*, 1983) appears to confirm this observation, although the size and generality of the effect is difficult to assess due to the high drop-out rate from both the imipramine-treated group (29%) and the control group. Also, patients had phobias with panic attacks rather than generalized anxiety with panic attacks.

If imipramine does suppress panic attacks, how might this come about? Two clinical observations are relevant. Firstly, many anxious patients complain of unpleasant side-effects when they first take imipramine even in small doses (Zitrin *et al.*, 1978). Although the point has not been tested formally, it is reported that these side-effects are more severe than those experienced by most depressed patients; thus Zitrin (1983) states that some patients are exquisitely sensitive to the drug, developing insomnia, irritability, unusual energy and apprehension with doses as low as 10 mg/day. Secondly, it appears that the anti-panic effect is slow to develop, taking up to four weeks before panics cease (Zitrin, 1983). This contrasts with the early onset of side-effects.

These clinical observations can be compared with pharmacological findings about imipramine and related antidepressants. The immediate effect of these drugs is to block the re-uptake of noradrenaline, thereby increasing the amount of noradrenaline acting post-synaptically. This action could account for the side-effects noted early in treatment. The subsequent changes are quite complex. Long-term administration of tricyclic antidepressants reduces post-synaptic β -adrenergic receptor function and increases post-synaptic α_2 adrenergic function (Charney *et al.*, 1981). Also, chronic administration of some tricyclic antidepressants decreases α_2 adrenergic autoreceptor function (Charney *et al.*, 1981). The net effect of these changes on noradrenergic function is extremely difficult to predict. One way around this difficulty is to assess overall transmission through the synapse. Cowen *et al.* (1985) have studied transmission through adrenergic synapses using the release of melatonin as an index of this (the release of melatonin in the pineal depends on noradrenergic transmission). These experiments show that in normal subjects after desmethylinipramine has been taken there is an initial increase of adrenergic transmission which lasts for at least a week; after three

weeks of treatment it returns to the pre-treatment level. This return to normal despite continuing treatment suggests some kind of compensatory mechanism that overcomes the effect of the initial rise in noradrenergic transmission. If, as seems likely, imipramine has effects similar to those of desmethylinipramine this compensatory mechanism might have an effect that stabilizes adrenergic synapses. If that were the case, it might also account for the anti-panic effect.

Cowen *et al.* (1985) studied normal subjects, and comparable data are not available from patients with panic attacks. However, Charney & Heninger (1985) have reported decreased MHPG concentrations in the plasma of such patients after 8–12 weeks of imipramine. This finding suggests that central noradrenergic function has been reduced by the drug. The mechanism is not understood, but Charney & Heninger suggest that it is not mainly due to changes in α_2 receptors, since responses to yohimbine (which acts on these receptors) are unchanged.

As yet these ideas are speculative, because we do not know how this compensation is brought about. However, this is an obvious area for research, and the answer might increase our understanding not only of the actions of imipramine in patients with panic attacks but also the abnormality in nervous regulation that is present in these patients.

Hyperventilation as a cause of panic attacks

An increase of respiratory activity is part of the normal 'fight or flight' response. Patients with anxiety neurosis increase their breathing as well as their level of sympathetic arousal and, since they engage in neither fight nor flight, they may breathe off more CO_2 than they produce (i.e. hyperventilate). Hyperventilation produces symptoms resembling those of panic anxiety, as can be seen when the symptoms of the two conditions are listed in parallel (Table). It is possible that panic attacks occur when the symptoms of hyperventilation occur alone or when they are added to the other manifestations of an anxiety response which would otherwise produce less intense symptoms.

The most direct way of deciding whether panic attacks are caused by hyperventilation is to estimate concentrations of carbon dioxide in arterial blood (paCO_2) during a panic attack. These concentrations can be estimated indirectly in a laboratory by measuring end-tidal CO_2 or directly by intra-arterial sampling. However, panic attacks seldom occur in the controlled conditions of the laboratory.

Until recently it was not possible to make measurements of paCO_2 during panic attacks occurring

TABLE I
Comparison of symptoms of panic attacks and hyperventilation

<i>Diagnostic criteria for panic attacks¹ (at least four required)</i>	<i>Symptoms of hyperventilation²</i>
Dizziness, light-headedness or unsteady feelings	Dizziness
Depersonalization or derealization	Unreality
Faintness	Faintness
Paraesthesiae	Paraesthesia
Trembling and shaking	Tremor and coarse twitching
Shortness of breath or smothering sensations	Shortness of breath
Palpitations or tachycardia	Palpitations
Chest pain or discomfort	Atypical chest pain
Apprehension	Apprehension
Choking	
Sweating	
Nausea and abdominal distress	
Hot flushes or chills	
Fear of dying	
Fear of going crazy or of doing something uncontrolled	

1. From DSM-III-R (American Psychiatric Association, 1985)

2. From Lewis (1954)

outside the laboratory, but a method has now been described which can estimate paCO_2 indirectly in ambulant patients. Hibbert (1986) has combined a miniaturized method for measuring transcutaneous CO_2 , developed at University College Hospital, with the Medilog recorder, which was originally developed for 24-hour monitoring of ECG. The principle is this: the rate at which CO_2 leaks through the skin depends on paCO_2 , skin metabolism and skin blood flow. The last two can be held constant in the skin under a pH electrode by warming that skin to a constant temperature. Under these circumstances measurements of pH reflect transcutaneous CO_2 leakage, and have been shown to be highly correlated with paCO_2 (Clutton-Brock & Rithalia, 1984). Using this method, Hibbert has shown that some patients hyperventilate during panic attacks. Not all do this, however, and it is not yet certain what proportion of panic attack patients do. On the present evidence it seems that although hyperventilation may contribute to panic attacks in some patients, it is not likely to be the principal cause in the majority.

Psychological causes of panic attacks

The psychological mechanisms involved in anxiety are no less complicated than the physiological ones. However, for the present discussion it will be enough

to consider one important psychological component: the cognitive changes.

Paradoxically, the psychological theory of panic attacks begins with the results of pharmacological experiments. It has been explained that panic attacks can be provoked by voluntary overbreathing and that yohimbine, an alpha-adrenergic blocker, has a similar effect. It is also well-known that infusions of sodium lactate provoke panics, and do so more readily in anxious patients than in normal subjects (Pitts & McClure, 1967). The mild stimulant caffeine has a similar effect (Boulenger *et al.*, 1984). These observations could be explained if the various agents have the common pharmacological property of stimulating activity in the locus ceruleus (or some other structure controlling anxiety). However, there is an equally plausible alternative explanation, which is worth considering because not all panic attack patients who receive these provoking agents respond by developing a panic: psychological factors may account for the variability in response.

This psychological explanation starts with observations on individual differences in response to one of the provoking agents—hyperventilation. Clark & Hemsley (1982) asked volunteers to overbreathe and recorded three variables: the symptoms experienced, the pCO_2 level reached, and the neuroticism score of each patient. Physical symptoms, especially

palpitations, were quite highly correlated with the lowering of $p\text{CO}_2$ achieved during hyperventilation, while psychological symptoms were related more to measures of neuroticism. Clark & Hemsley suggested that there might be a two-stage process in which overbreathing leads to physical symptoms, which in turn give rise to worries that increase the level of anxiety further. They pointed out that a response of this kind could readily give rise to a vicious circle leading to a panic attack.

Neuroticism is a broad concept; can the psychological component be identified more precisely? It was noted earlier that Freud (1895) stressed the anxious patient's preoccupation with fears of dying, a stroke, or loss of sanity. Beck *et al* (1974) drew attention to similar symptoms, and added fears of heart disease and fainting. Hibbert (1985a) assessed all these fears in a standardized way and confirmed the earlier observations. Of course, the fears might be a consequence of the panic attacks rather than a cause. This problem can be addressed most readily by attempting to treat panic attacks by changing the cognitions with a psychological treatment.

Clark *et al* (1985) have described a treatment in which cognitions are changed by combining voluntary hyperventilation, intended to provoke symptoms, with cognitive restructuring in which it is explained how panic attacks can result from the misinterpretations of bodily sensations resulting from overbreathing and other innocuous causes. Patients then practise controlling these attacks both in subsequent occasions of treatment and during panic attacks arising occurring in everyday life. Two clinical trials have shown that this treatment leads to a substantial improvement in panic attacks in patients who did not improve during a preliminary waiting period (Clark *et al*, 1985; Salkovskis *et al*, 1985). A stricter test of a randomized comparative trial will have to be carried out before these findings can be evaluated fully. However, the existing evidence does seem to give quite strong, although necessarily indirect, support to the cognitive theory of panic attacks.

Conclusion

The various mechanisms for the cause of panic attacks which have been reviewed are not mutually exclusive: they are concerned with different stages of a complicated psychophysiological process which could go wrong in more than one way. Just as we now recognise more than one cause of hypertension or diabetes, so we may need to recognise more than one cause of panic attacks.

There is no support for the theory that peripheral β -adrenergic mechanisms are hypersensitive in patients with panic attacks. Although there are interesting pointers to a possible disorder of the central mechanisms controlling sympathetic activity, there is as yet insufficient firm evidence to support this hypothesis strongly. Nevertheless, this is clearly one of the more promising lines for future research. There is no convincing evidence that the majority of attacks are principally caused by hyperventilation, though overbreathing may play a part in some attacks—it is still not known how many.

The psychological hypothesis that cognitions are abnormal in people who experience panic attacks and that these cognitions amplify the anxiety response is quite strongly supported by evidence, albeit mostly indirect evidence. The idea receives further support from the effects of a cognitive treatment, though the specificity of the effect has not yet been established beyond doubt.

We are still some way from solving the problem of panic attacks which Freud drew to our attention. Nevertheless, much progress has been made in recent years towards a better understanding of the causes, and it seems likely that the eventual solution will be of a particularly interesting kind, integrating pharmacological, physiological and psychological approaches to the problem.

Schizophrenia therapy: the importance of balance

Too often, neuroleptic therapy swings the mood of the schizophrenic patient too far. Withdrawn patients' moods can be raised so high that they become agitated; whilst agitated patients may sink so low that they become withdrawn.

Experience shows that Piportil Depot treatment usually gets this critical balance right. Successful resocialization has been achieved even in patients who respond poorly to other neuroleptics.¹

Piportil Depot contributes to putting the patient back into everyday life in other ways, too. Thanks to its relative freedom from extra-pyramidal effects,²⁻⁵ and because injections need only be given every four weeks, patients hardly know they are being treated.

Piportil

DEPOT PIPOTHIAZINE PALMITATE

Piportil Depot Prescribing Information

Dosage: (Adults) Initially 25mg (0.5ml) by deep intramuscular injection into the gluteal region to assess susceptibility of patient. Dosage should be increased by increments of 25 to 50mg at appropriate intervals until a satisfactory response is obtained. Most patients respond to a dose of 50-100mg (1-2ml) every 4 weeks. Patients should be stabilised under psychiatric supervision. **Contra-indications:** Marked cerebral atherosclerosis, phaeochromocytoma, renal or liver failure, severe cardiac insufficiency or hypersensitivity to other phenothiazine derivatives. **Precautions:** A history of convulsive disorders or marked extra-pyramidal reactions to oral phenothiazines, in pregnancy and lactation. **Side-effects:** Reversible extra-pyramidal reactions, sleep disturbance, depression, blurred vision, asthenia, impotence, dry mouth, nausea, amenorrhoea, galactorrhoea, hypotension,

hyperhydrosis and weight gain have been observed occasionally. Corneal or lenticular cloudiness have not been observed with Piportil alone, but in treatment with phenothiazine preparations in high dosage over a long period, there is a risk of such side-effects occurring. Local reactions at site of injection are rare. **Presentations and Hospital Prices:** Boxes of 10 x 1ml (50mg) £48.33 and 10 x 2ml (100mg) £79.08; ampoules (PL0012/0117). **References:** 1. When depression is the source of anxiety...

PROTHIADEN

Dothiepin Hydrochloride B.P.

restores peace of mind

Differential diagnosis of depression and anxiety is rarely clear cut. Your typically middle-aged female patients will usually present with symptoms of both. The potential risks of an inappropriate choice of treatment for these patients can often be a cause for concern.

Prothiaden, with its well-proven ability to relieve both depression and anxiety, can alleviate this concern. A prescription for Prothiaden ensures that neither aspect of your patients' problem is left untreated.

So, in this complex diagnosis, Prothiaden has an additional benefit – relieving your anxiety as well as that of your patients.

PRESCRIBING INFORMATION

Presentation: Prothiaden is Dothiepin Hydrochloride B.P., an antidepressant of the tricyclic group. It is available as 25mg capsules and 75mg tablets. **Uses:** Prothiaden is indicated in the treatment of depression and associated anxiety. **Dosage:** Prothiaden should be given in a dosage of 75 to 150mg daily, based on response and severity. This may be taken as a single evening dose. In certain circumstances, i.e. in hospital use, Prothiaden has been given in dosages up to 225mg daily. Elderly – half the normal adult dose may be sufficient. **Precautions and Contra-indications:** Prothiaden has anticholinergic properties, therefore, it may precipitate urinary retention in susceptible individuals and its use should be avoided in patients with existing or potential urinary retention. Prothiaden should not be used in patients with closed-angle glaucoma. Caution is advised when treating epileptic patients and those with cardiovascular disorders. Prothiaden should not be used with MAO inhibitors nor within 14 days of ceasing such treatment. It may modify the action of some CNS depressants, catecholamines and hypotensive agents. **Side Effects:** These are usually mild and normally controlled by reducing the dosage. The following have been reported: dryness of mouth, constipation, disturbed accommodation, orthostatic hypotension, palpitations, somnolence, tremor, headache. **Basic N.H.S. Price:** 28 x 75mg £3.73. **Product Licence Numbers:** PL0014/5941, PL0014/0209. © The Boots Company PLC, Nottingham, England. Further information available on request.

Gamma Glutamyl Transpeptidase and Mean Corpuscular Volume: Their Usefulness in the Assessment of In-Patient Alcoholics

R. W. LATCHAM

Gamma glutamyl transpeptidase and mean corpuscular volume are shown to be of little value in the assessment of patients admitted to psychiatric beds for problem drinking.

The measurement of serum gamma glutamyl transpeptidase (GGT) and mean cell volume (MCV) as markers of alcohol consumption has become widespread in surveys of alcohol abuse (e.g. Chick *et al.*, 1981), and as a matter of routine in patients admitted for alcoholic diagnoses. MCV, raised by the direct toxic effect of alcohol on erythropoiesis, reflects long-term drinking habits. GGT, by contrast, is an enzyme, predominantly microsomal in location, which is raised in approximate proportion to recent alcohol consumption. After cessation of drinking the plasma enzyme level returns to within normal range in 3-6 weeks in an exponential fashion (Lamy *et al.*, 1975; Waldstein & Skude, 1979). Morgan (1980) has reviewed the use of these and other markers for detecting and monitoring alcohol abuse. Like others (Chick *et al.*, 1981; Madden & Krasner, 1984) she concludes that although markers in combination are of some use in the routine screening and monitoring of alcoholics, "no simple reliable marker for alcohol abuse exists currently". The poor sensitivity and specificity of both GGT and MCV are discussed by Chick *et al.*, who describe in particular the effects of other illness and drugs on both GGT and MCV, of age and weight on GGT, and of smoking on MCV.

In the present study the correlations of these two markers with a number of variables associated with severity of alcohol dependence or abuse were determined in a large group of patients admitted to psychiatric beds for alcohol dependence. In addition, proportions of the groups identified by the tests separately and in combination were determined, and subjects with and without one or both tests in the 'abnormal' range were compared. It was then possible to describe the sensitivity of the tests and their usefulness as an adjunct to clinical assessment of problem drinkers.

Method

The subjects were first admissions to a psychiatric hospital in 1981-1982, and diagnosed by their admitting psychiatrist

as having the alcohol dependence syndrome, ICD9 category 303 (World Health Organisation, 1979). Three treatment centres (Inverness, Montrose and Canterbury) were selected for the purposes of this and other studies reported elsewhere (Latcham *et al.*, 1984; Latcham & Kreitman, 1985; Latcham, 1985). Samples were consecutive except for those whose length of stay in hospital was so short that contact was not possible.

A total of 190 men and 47 women were interviewed using a standardised instrument in which extremely high inter-rater reliability, already demonstrated by Chick (1980), was obtained by the author and three trained interviewers. Eleven males and two females were excluded at this stage because of serious physical illness not attributed to alcohol, or because they were taking anticonvulsants (including chlormethiazole and barbiturates). For the remaining 179 men and 45 women various items and scores were derived from their interview concerning

- (a) age, weight and smoking habits
- (b) consumption of alcohol during the last week before admission, and during a typical week from the past three months (if the last week was atypical) using the one week retrospective diary method
- (c) the Edinburgh Dependence Schedule (Chick, 1980) from which two measures of alcohol dependence were derived: one categorical (dependent or not) and one measuring severity of dependence on a continuous basis (the number of symptoms of dependence present in the past three months added to form the Edinburgh Alcohol Dependence score)
- (d) a history of health problems reported by patients to have occurred in the past two years. Problems were required to be ascribed by the respondent to alcohol consumption. A health problem score was derived by adding the number of problems which included neuropathy, alcoholic hepatitis and cirrhosis, fits, impotence and chronic diarrhoea.

MCV was measured using Coulter-S counters, and GGT according to the method of Szasz (Szasz & Persija, 1974). The number of days that had elapsed between cessation of drinking and the sampling of blood was recorded. The presence of hepatomegaly was determined by abdominal palpation in a subsample of 66 men and 16 women.

TABLE I
Means and standard deviations of variables by sex

Variable	Mean (<i>n</i> = 179)		Women (<i>n</i> = 45)	
	Mean	s.d.	Mean	s.d.
Alcohol consumption in week before admission ¹ : units of alcohol ²	183	131	111	80
Alcohol consumption in typical week: units of alcohol	185	120	114	74
Alcohol dependence score	27.5	11.5	25.7	10.0
Health problem score	2.6	1.5	2.5	1.5
GGT: iu/l	128	188	146.6	280
MCV: fl	95.7	5.9	97.8	7.9
Age: years	40.4	11.5	41.4	10.9
Days elapsed between last drink and blood sampling	4.2	9.1	3.2	4.8

1. For this variable *n* = 153 (males), 42 (females) (not all patients drank in the last week).

2. 1 unit = one half pint of ordinary beer or equivalent.

Analysis

Analyses of two kinds were performed. Firstly, the subjects were divided into two groups, according to whether their GGT was above or below 50 international units/litre (iu/l). The two groups were compared for mean alcohol consumption, mean number of alcohol-related health problems, mean alcohol dependence score, proportion with and without dependence, and (in the subsample) hepatomegaly. This analysis was repeated six times using varying criteria for GGT and MCV to divide the sample. Each sex was analysed separately. A number of patients (36 men and 7 women) were excluded from analyses concerning GGT because they were taking regular paracetamol, opiates or amphetamine, or because they had last drunk alcohol more than 14 days before their blood was sampled.

Secondly, after log transformation of the data, correlations between alcohol consumption, severity of alcohol dependence, health problem scores, MCV and GGT were calculated; 28 males and 6 females who took opiates, amphetamines or regular paracetamol were excluded, leaving 151 men and 38 women for this analysis. These correlations were recalculated controlling for the effects of age, weight, smoking and number of days between last drink and blood sampling.

Results

The means and standard deviations of measured variables are shown in Table I for the complete sample. In addition, 41 of the 179 men and 7 of the 45 women were found not to be alcohol dependent. In the subsamples whose abdomens

were examined, 26 of 66 males and 4 of 16 females had palpable hepatomegaly. 81% of the men and 92% of the women smoked.

The sensitivities of GGT and MCV (at each cut-off value) are shown in Table II, both separately and in combination. Less than three-quarters of both men and women were identified as having either GGT > 50 iu/l or MCV > 96 fl. Less than a third of either sex had results for both these tests in the 'abnormal' range.

Analysis showed that in neither sex were there significant differences between groups however they were categorised, using two-tailed *t*-tests for continuous variables (severity of dependence, alcohol consumption both in a typical week and week before admission and health problem score), and chi-squared or Fisher's exact test for categorical variables (hepatomegaly and presence or absence of dependence). There were two minor exceptions: males with an MCV above 96 fl were significantly more likely to have hepatomegaly (Fisher's exact test $P < 0.01$), and males with an MCV above 96 fl drank significantly more the week before admission ($t = 4.99$, d.f. 1, 151, $P < 0.05$).

The correlation matrices are shown in Table III. When age, smoking, weight and days elapsed between last drink and blood sampling are controlled, only the negative correlation in women between health problem score and the consumption of alcohol in the week before admission becomes significant at the one in twenty level; otherwise there are no effects either for the men or the women. GGT and MCV are not significantly correlated with any variable for women, and only with each other for males. For both sexes the alcohol dependence score is positively correlated with alcohol consumption in a typical week, and with the health

TABLE II
Percentages of sample by sex identified at various levels of blood results

Blood level criteria	Males			Females		
	n	Sample size	%	n	Sample size	%
GGT > 50 iu/l	83	143	58.0	12	38	31.6
MCV > 96 fl	82	179	45.8	24	45	53.3
MCV > 98 fl	58	179	32.4	21	45	46.7
GGT > 50 iu/l or MCV > 96 fl	102	143	71.3	24	38	63.2

problems score. No item in the health problem score was included in the alcohol dependence score, which in turn did not include a measure of consumption.

Discussion

With reference to Table I, the absence of correlations between MCV or GGT and clinical measures of severity of alcohol-related problems might be considered to be the result of the narrow range of variables which might be expected in a group of problem

drinkers so severe that they required in-patient treatment. However, this is not the case; the range of all variables was considerable.

It might also be suggested that the self-reports of problem drinkers are unreliable in their accounts, both of quantity consumed and extent of symptoms. The significant correlations obtained for both sexes between a measure of consumption, the alcohol dependence score, and the health problems score militates against such a suggestion. Unexpectedly,

GGT and MCV do not reflect severity of dependence, consumption of alcohol, or the extent of alcohol-related health problems. Also, patients of either sex, divided into groups according to the results of their blood tests in various ways, did not differ on most clinical variables measured.

Conclusion

In this study, the results of GGT and MCV do not identify more than about two thirds of patients even when the tests are taken in conjunction. Neither test identifies problem drinkers who are more severely

dependent, or who drink more. Neither test correlates with severity of dependence, with reported alcohol consumption, or with the extent of alcohol-related health problems. Although, as many have suggested (Rosalki, 1977; Morgan *et al*, 1981; Chick, 1983), serial values of GGT and MCV may be useful in monitoring the progress of problem drinkers, these tests are unlikely to add to the initial clinical assessment of such patients.

Modecate Abbreviated Prescribing Information. **Indications:** Treatment of psychotic disorders. **Dosage – Modecate injection 25mg/ml.** Most patients are successfully maintained within the dosage range 12.5mg (0.5ml) every five weeks to 100mg (4ml) every two weeks. For full dosage information see Data Sheet. **Modecate concentrate injection 100mg/ml.** Adult patients found to require larger volumes of Modecate 25mg/ml may be transferred directly to the equivalent dose of Modecate concentrate on the basis that 1ml Modecate concentrate is equivalent to 4ml Modecate. **Contra-indications.** Patients with marked cerebral atherosclerosis, pheochromocytoma, renal or liver failure, or severe cardiac insufficiency. **Precautions.** Care should be taken in patients, particularly the elderly, who exhibit marked extrapyramidal reactions to oral phenothiazines. **Side effects.** Mainly extrapyramidal reactions. Drowsiness, lethargy, dryness of the mouth and mild hypotension may occur. **Product Licence No's and Prices.** **Modecate injection 25mg/ml.** PL 0034/5046. 10 x 1ml ampoule £25.20 **Modecate concentrate injection 100mg/ml.** PL 0034/0189. 10 x 0.5ml ampoule £49.99 10 x 1.0ml ampoule £48.86. Modecate is a Trade Mark of E. R. Squibb & Sons Ltd. Further information available from: Technical Services Department, E. R. Squibb & Sons Ltd., 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. Tel: 01-572 7422.

TRIED AND TRUSTED

19 years ago, E. R. Squibb & Sons helped lead a revolution in the community based treatment of schizophrenia when they introduced the depot neuroleptic concept. Since then worldwide clinical experience has confirmed the efficacy and safety of Modecate in over 800,000 patients.

Modecate is now regarded by many psychiatrists as the standard depot neuroleptic.

Modecate is available in two strengths, allowing a wide dosage range with convenient injection volumes. Most patients can be controlled with an injection at intervals of 3 weeks or more! Modecate is less expensive than other depot neuroleptics when comparing equivalent doses.

The alternative to tardive dyskinesia?

Effective first line therapy with no reports of tardive dyskinesia when used alone.

Dolmatil is as effective as chlorpromazine,¹ trifluoperazine² and haloperidol³ but when used alone, in the absence of previous treatment with conventional neuroleptics, it has not been associated with tardive dyskinesia⁴

DolmatilTM
sulpiride
IN SCHIZOPHRENIA

Prescribing information Dolmatil Tablets: Plain white round tablets with a transverse breaking line on one side and the mark D200 on the other. Each tablet contains 200mg sulpiride. **Indications:** Acute and chronic schizophrenia. **Dosage:** A starting dose of 400mg to 800mg daily, given as one or two tablets twice daily (morning and early evening) is recommended. **Predominantly positive symptoms:** Starting dose of at least 400mg twice daily, increasing if necessary up to 1200mg twice daily. **Predominantly negative symptoms:** Starting dose of 400mg twice daily reducing as required towards 200mg twice daily. **Mixed positive and negative symptoms:** 400mg-600mg twice daily. The same dose ranges may be required in the elderly, but should be reduced if there is evidence of renal impairment. Clinical experience in children under 14 years of age is insufficient to permit specific recommendations. **Contraindications:** Phaeochromocytoma. **Warnings:** Extrapyramidal reactions principally akathisia have been reported in a small number of cases. If warranted, reduction in dosage or anti-Parkinsonian medication may be necessary. After over a decade of widespread use in many countries, tardive dyskinesia has occurred rarely, insomnia has been reported, increased motor agitation has been reported at high dosage in a small number of patients. In aggressive, agitated or excited phases of the disease process, 'Dolmatil' may aggravate symptoms. Care should be exercised where hypomania is present. Galactorrhoea, amenorrhoea and gynaecomastia may occur in association with hyperprolactinaemia. **Precautions:** Epilepsy - anti-convulsant therapy should be continued unchanged. Impaired renal function, as sulpiride is eliminated via the kidney. Pregnancy - the general principle of avoiding drug treatment during pregnancy, particularly during the first sixteen weeks, should be followed. **Product Licence Number:** PL 5299/0006. **Legal category:** POM. **Basic NHS cost:** 63p per day at dose of 600mg daily. **Name and address of Distributor:** E R Squibb & Sons Ltd, Squibb House, 141-149 Staines Road, Hounslow, Middlesex TW3 3JA. ***Trade Marks of E R Squibb & Sons Ltd (Distributor) DOLMATIL - Trade Mark of SESIF Authorised User Delagrangue Ltd. A Survey of Practising Psychiatrists' Views on the Treatment of Schizophrenia

S. ANDREWS, K. VAUGHAN, R. HARVEY and G. ANDREWS

Practising psychiatrists' views about the treatment of schizophrenia were investigated as part of a Quality Assurance Project. A questionnaire which asked for treatment recommendations for each of four case descriptions of patients with schizophrenia was mailed to a one-in-six random sample of Australian psychiatrists; 90% responded. Psychiatrists almost uniformly advocated the use of antipsychotic drugs and usually recommended concurrent supportive psychotherapy or family/social intervention procedures. The recommendations varied systematically, according to the initial history obtained and to the initial response to treatment.

The aim of the Quality Assurance Project is to write a set of outlines for the treatment of the common psychiatric disorders, using three sources of information: the research literature on outcome of treatment, the views of a sample of practising psychiatrists, and the views of persons nominated as experts in the treatment of the disorder under study (Quality Assurance Project*, 1982a & b, 1983). This report summarises the results of the survey of practising psychiatrists' recommendations concerning the treatment of schizophrenia. The treatments recommended for different types of patients with schizophrenia are compared, and these recommendations are evaluated in relation to the treatment guidelines formulated by the panel of experts (Quality Assurance Project, 1984), which concluded that

"The three sources of information agree that antipsychotic drugs are the principal treatment during the active phase of the disorder. As schizophrenia is so often a serious and disabling chronic illness, the treatment recommendations stress the need for continuity of care during the post-acute and residual phases in order to prevent relapse and minimise residual deficits. The outlines particularly emphasise the consistent but conservative use of antipsychotic drugs, and the implementation of a specific type of family management programme in addition to the customary social interventions".

Method

The general issues involved in surveying medical practitioners' preferred methods of treatment have been

*Quality Assurance in Aspects of Psychiatric Practice is a project under the aegis of the Royal Australian and New Zealand College of Psychiatrists, funded by the Australian Department of Health. Director: Gavin Andrews.

discussed elsewhere (Quality Assurance Project, 1982b; Hall *et al.*, 1982). The essential conclusions were that the wide geographical distribution of the sample demanded a questionnaire format, and that the questionnaire should specify diagnosis, in order to reduce the confounding of diagnostic issues with treatment recommendations.

The questionnaire

Four 350-word case vignettes were constructed. *Case 1* was a withdrawn and suspicious 19-year-old youth suffering from his first episode of schizophrenia, paranoid type (DSM-III). He had shown prodromal signs of social withdrawal and role deterioration since early adolescence. He lived with his highly critical father and anxious overprotective mother. *Case 2*: a female aged 19 suffering from her first episode, characterised by sexual delusions and auditory hallucinations. Unlike the first patient, premorbid development was normal, with no evidence of a prodrome, so that the DSM-III diagnosis was schizophreniform disorder. Her father had died when she was 12, but her mother appeared warm, concerned and co-operative.

Case 3 was a 53-year-old married woman with three teenage daughters, who had an 18-year history of recurrent episodes of schizophrenia, undifferentiated type (DSM-III), reflected in chronic thought disorder, labile affect, and poor concentration between episodes and periodic exacerbations of acute psychotic symptoms. She had had eight previous hospitalisations and despite continual phenothiazine medication, her condition caused considerable tension and disruption for her family. The same diagnosis had been applied to *Case 4* who was a 28-year-old invalid pensioner with a six-year history of chronic fixed grandiose delusions. Completely lacking in social support and chronically impaired in his functioning, he had a history of recurring hospitalisation and of contact with local psychiatric, social and police agencies. A recent decrease in medication had resulted in signs of tardive dyskinesia, which had disappeared when the dose was raised again.

The first two cases represented first presentations of illness, which were distinguished from each other by the presence or absence of prodromal symptoms and the differing nature of their delusions, while the third and fourth cases were chronic patients who differed principally in their degree of residual impairment and in the presence of social support.

For each case, respondents were asked to specify the components of their treatment plan at three points in time: at initial presentation, one month later, presuming a positive response to initial treatment (no 'improved' description was provided for Case 4), or alternatively, three months later, presuming little or no response to the initial treatment. Treatment components were to be selected from a glossary of 132 different treatment components, grouped under the following major headings:

TREATMENT LOCATION

Pharmacotherapy

Antidepressants
Major tranquillisers
Antiparkinsonian agents
Anxiolytics
Sedative/hypnotics
Vitamins and hormones
Electroconvulsive therapy

Psychotherapies

Individual therapies
Group therapies
Family therapies
Use of adjunctive therapists

Referrals

Other professionals
Specialized day programmes
Residential changes

Each category was further specified so that there were, for example, brief descriptions of ten types of psychotherapy and nine types of family therapy to allow psychiatrists to specify the details of their treatment. The layout of the questionnaire allowed respondents to indicate the relative time course of the introduction of the various components of each treatment plan. As well as specifying their treatment plans, psychiatrists were asked about the number of patients of each type they saw, whether involuntary treatment or referral was indicated and the anticipated length and frequency of treatment.

The sample

Essentially the same sample of practising psychiatrists has been surveyed for each phase of the Quality Assurance Project. In 1981, this sample was drawn from a consolidated list of the 1154 psychiatrists practising in Australia. By 1983 (the time of the schizophrenia questionnaire), 23 psychiatrists from the original sample had died, retired,

moved overseas, or withdrawn. These were replaced with predetermined substitutes, resulting again in a total sample of 193, from whom 173 codable questionnaires were received.

Results

Sample characteristics

Of the respondents, 78% were male. Their median age was 46, and half were between 39- and 55-years-old. The median year of qualification (MB.BS) was 1962; 71% had obtained their psychiatric qualifications in Australia, 22% in Britain, 3% in New Zealand and 5% elsewhere; 85% of the sample were members of the Royal Australian and New Zealand College of Psychiatrists and 36% had double qualifications (e.g. British DPM and Australian membership). Of the sample 58% identified themselves as being in private fee-for-service practice, the remainder being in salaried university or public sector employment. The majority (70%) of those in public practice worked in institutionally-based inpatient or outpatient facilities. The median percentage of time that the sample as a whole spent in clinical contact with patients was 80%, indicating that they were, as intended, a group of practising psychiatrists.

Method of analysis

Merely listing the frequency of various treatments recommended for each case is an exercise of little interest. Instead we have, in addition, compared treatments across and within cases across time. Where possible, we have commented on factors which may have influenced these differing recommendations. The method of analysis used was to test mutually orthogonal linear contrasts. For across-case comparisons, the contrasts tested compared the two acute patients (Cases 1 and 2) with the two chronic patients (Cases 3 and 4); then the two acute cases were compared with each other to see if treatment strategies differed according to premorbid history; and finally, the two chronic cases were contrasted to investigate differences in response to the chronicity of residual impairment. The within-case contrasts investigated differences between recommendations made initially and those made one month later, when the patient had improved (this comparison could not be made for Case 4); and between initial recommendations and those made three months later, when the patient had failed to improve with the initial treatment recommended.

For the purpose of performing statistical tests, the contrast coefficients were applied to the logarithms of the cell frequencies. This procedure derives from the log linear model of categorical data (Fienberg, 1978; Goodman, 1964) and is equivalent to testing whether the odds ratio corresponding to a particular contrast could have arisen by chance. Because the resulting analysis involved conducting multiple tests, the Bonferroni inequality (Miller, 1966) was used to adjust the critical value for each test, to ensure that the Type I error rate for the set of decisions was not inflated by the number of tests conducted (Bird, 1975).

TABLE I

The percentage of the sample who said, for each case, that (1) "involuntary treatment was indicated" and that (2) "they would refer" to other practitioners and that (3) they would treat in hospital initially, if improved after one month or if unimproved after three months treatment

	Case 1 %	Case 2 %	Case 3 %	Case 4 %	Average %
(1) Involuntary treatment indicated	17	5	56	42	30
(2) Referral indicated	27	14	52	49	36
(3) Initial	60	47	92	25	66
If "improved"	19	4	5	—	9
If "unimproved"	48	52	27	41	54

Questionnaire results

Involuntary treatment, referral and hospitalisation

The proportions of the sample who indicated that they did not see involuntary treatment as warranted in a particular case, or who reported that they would refer the patient rather than treat themselves, are presented in Table I.

Analysis of these data revealed that psychiatrists were more likely to recommend involuntary treatment for the chronic than the acute cases ($z = 10.68$; $P < 0.001$). Of the two acute cases, involuntary treatment was more frequently seen as indicated for Case 1, whose premorbid development was poor, than for Case 2 ($z = 6.89$; $P < 0.001$). Within the chronic cases, psychiatrists were more likely to recommend involuntary treatment for Case 3, whose episodes were recurrent and disturbing to the family, than for Case 4, who was chronically delusional and disturbing to society ($z = 8.89$; $P < 0.001$).

Referral elsewhere was more likely for the chronic than the acute cases ($z = 8.27$; $P < 0.001$). Psychiatrists were significantly more likely to treat the good premorbid acute case than the acute patient with a poor premorbid history ($z = 3.02$; $P < 0.01$). The frequency with which in patient hospital care was recommended after initial interview, after one month presuming improvement, or after three months presuming no improvement, are given in Table I. The major unexpected finding was that, of the two chronic cases, Case 4, without family support and with a poor prognosis, was less often hospitalised ($z = 3.7$; $P < 0.01$).

Frequency of consultations

Psychiatrists were asked how many consultations they expected to have with the patient alone, the family alone, and conjointly in the first three months of treatment. The median values obtained for each case were compared but the differences were evaluated in terms of the overlap between confidence intervals around these medians

(Snedecor & Cochran, 1937). Psychiatrists expected to have more consultations with acute cases and their families than with chronic cases, more consultations with Case 2 than Case 1, and with Case 3 than Case 4. The overall difference in the frequency of consultations for the two chronic cases was purely a function of family and conjoint consultations, presumably because Case 4 was described as having lost contact with his family. The difference between consultation frequency for the two acute cases was more complex, with psychiatrists indicating that they would have more patient consultations with Case 2 than Case 1, but more family and conjoint consultations with Case 1 than Case 2. These differences cannot be explained in terms of the availability of the family, since both case vignettes indicated that the family was involved in the referral. Rather, the frequency of family and conjoint consultations appears to be a function of the implied degree of conflict between patient and family, since they were more frequently recommended for Cases 1 and 3, where tension was implied, than for Case 2, where the mother was described as being co-operative and concerned.

Treatment plans

In order to facilitate comparisons of the treatment plans recommended for the four cases, recommendations were grouped to allow the testing of a number of mutually independent contrasts. Firstly, with regard to pharmacotherapy, the contrasts compared the proportion of psychiatrists recommending a drug alone with the proportions recommending no drug, and those recommending a drug in conjunction with some form of psychotherapy. Then, amongst those recommending the use of drugs, comparisons were made of the proportions recommending low potency, high potency, and depot antipsychotic preparations.

Questions were then asked concerning the use of non-drug therapies. In retrospect, we did not think that the treatment glossary had allowed sufficient room, particu-

larly within the family therapy codes, for psychiatrists to demonstrate their preference for the newer family management techniques (e.g. Falloon *et al.*, 1982) recommended by the expert committee in schizophrenia (Quality Assurance Project, 1984). For the purpose of the treatment comparisons, therefore, recommendations for family therapy/counselling were combined with those for social interventions such as day programmes to give a joint estimate of family/social management. The contrasts evaluating non-drug therapies compared the proportions who recommended no non-drug therapy at all with those who did; the proportions recommending both psychotherapy and family/social techniques with those who recommended either procedure singly; and the proportions recommending psychotherapy with those recommending family/social interventions.

The percentage of the sample who recommended no drug, a drug alone, or a drug plus some form of psychotherapy are summarised in Table II. By far the most popular treatment was a combination of drug and other therapy. Initially, practitioners were more likely to recommend a drug alone than no drug, but the reverse was true when the patient had improved ($z=6.09$; $P<0.001$), and this was so for all cases. There was even an overall reduction in drug use when the patient failed to improve relative to initial presentation ($z=3.28$; $P<0.01$). The only significant difference between cases was that Case 4 was more likely than Case 3 to have a drug alone initially, whilst failure to improve resulted in a reversal in these proportions ($z=3.10$; $P<0.05$).

The percentage of psychiatrists whose drug therapy consisted of a low potency, high potency, or depot antipsychotic drug are summarised in Table III, for each case and each stage of treatment. Comparisons of the drugs recommended initially with those recommended following

improvements in symptomatology revealed that, overall, depot medications were recommended more frequently than either high or low potency short-acting antipsychotic drugs ($z=5.25$ $P<0.001$); this was more evident for Case 3 than for Cases 1 or 2. Recommendations for the two acute cases differed, in that high potency antipsychotics were more commonly recommended than low potency phenothiazines for Case 1 but not Case 2 ($z=3.64$; $P<0.01$), and that depot medications were relatively more commonly recommended for Case 1 than Case 2 ($z=3.56$; $P<0.01$).

The usage of depot medication was greater overall when the patient had failed to improve than initially ($z=5.24$; $P<0.001$), and this increase was proportionately greater for the acute than the chronic cases ($z=3.94$; $P<0.01$), although overall depot medication was more frequently recommended for the chronic than acute cases ($z=12.92$; $P<0.001$). Within the short-acting antipsychotic drugs, usage of high potency preparations was somewhat more common than of low potency ones for acute presentations of illness, while the reverse was true (although not to a level of statistical significance) for chronic patients ($z=2.85$). The only significant difference between the types of drugs recommended for the two acute cases was that depot medications were more common for Case 1 than Case 2 ($z=3.11$; $P<0.05$). Recommendations for the two chronic cases differed in that Case 3 was more likely to have low potency than high potency drugs recommended, while the reverse held for Case 4 ($z=3.84$; $P<0.01$), and that a failure to improve resulted in an increased frequency of depot medication for Case 3, but a decreased use of depot medication for Case 4 ($z=3.21$; $P<0.05$).

Non-drug therapies

The proportions of the sample who recommended only

TABLE II

The percentage of the sample recommending no drug, a drug alone, or a drug plus other concurrent therapy for each case and each stage of treatment: as initial treatment, if improved after one month of that treatment, or, if unimproved after three months of the initial treatment

	Case 1 %	Case 2 %	Case 3 %	Case 4 %	Average %

drug therapy, psychotherapy, family/social treatment, and both are summarised in Table IV. Non-drug therapies were popular ($z=6.77$; $P<0.001$), particularly the combination of psychotherapy and family/social interventions rather than either treatment in isolation ($z=6.83$; $P<0.001$), and especially after improvement had begun

($z=3.45$; $P<0.05$). The differences across cases centred mainly on the relative use of psychotherapy versus family/social treatment: family/social therapy was more frequently recommended for Case 3 than either Case 1 ($z=3.34$; $P<0.05$) or Case 2 ($z=8.77$; $P<0.001$); and for Case 1 than Case 2 ($z=7.19$; $P<0.001$).

When the patient had failed to improve, the chronic patients were less likely than acute cases to have both drug and non-drug treatments recommended concurrently ($z=5.13$; $P<0.001$) or to have psychotherapy alone recommended ($z=4.61$; $P<0.01$). Further, the bias towards psychotherapy for acute patients and family/social treatment for chronic patients, which was evident at initial presentation, was less marked when patients had failed to improve ($z=3.13$; $P<0.05$). There were no significant differences between the non-drug recommendations for the two chronic cases, and the only difference between the acute cases reflected the fact that psychotherapy was recommended more frequently than family/social therapy for Case 2 but not Case 1 ($z=7.34$; $P<0.001$).

Discussion

Schizophrenia is a serious mental illness from which only about 25% of patients recover completely (Quality Assurance Project, 1984). The symptoms during the active phase are usually unpleasant and frightening for both patients and their families, and the residual impairments of functioning, even in those whose psychotic symptoms remit, are often so severe that patients are unemployable and require continual care. It is presumably psychiatrists' recognition of these difficulties that prompted 36% to refer patients elsewhere for treatment, and for chronic patients, this figure was 50%. A significant proportion saw the need for involuntary hospitalisation for the two chronic cases, even though neither posed a danger to themselves or others—an attitude contrary to the thrust of current mental health legislation.

A summary of the recommended treatment plans at each stage, averaged across all cases (for the "improved" recommendations, averages represent only the first three cases), is presented in Table V. These figures indicate considerable consensus concerning the need for antipsychotic medication to control positive symptoms: only 2% of psychiatrists failed to include such drugs as an initial treatment component. There is also a recognition of the fact that some patients with schizophrenia may be able to do without medication when positive symptoms remit (overall 16% of the sample recommended no drugs when the patient had improved), particularly if the episode has had a sudden onset and a quick resolution, as was described for Case 2. Some sensitivity to the possibility that a failure to improve may indicate a resistance to drug treatment is indicated by the increased percentage recommending no drug in the "unimproved" (8%) than the initial (2%) treatment stage.

Recommendations for particular types of drugs appear to be tailored to the individual patient. Besides the obvious preference for depot medications for the chronic patients, psychiatrists also demonstrated differential usage of low versus high potency antipsychotic drugs. These differences reflect the drug's sedative properties, because the less sedating high potency preparations were initially more common for Case 1 who was socially withdrawn than for Case 2 who was not. Psychiatrists showed a preference for thioridazine over chlorpromazine at *all* stages of treatment for Case 2 but for Case 1 they recommended chlorpromazine more frequently than

TABLE V

thioridazine, even though skin photosensitivity is a problem in Australia.

Comparison of the dosages recommended for the most commonly recommended preparations, expressed in chlorpromazine equivalents and averaged over all cases (Table VI) revealed, as might be expected, lower dosage recommendations when the patient had improved. Thus, practising psychiatrists appear to agree with the expert committee in schizophrenia (Quality Assurance Project, 1984) that "the guiding principle in drug therapy is to get the dosage as low as possible". Also in accord with the recommendations of the expert committee is the fact that only 15% of the sample recommended that antiparkinsonian medications be used prophylactically, i.e. as an initial treatment.

Whilst antipsychotic drugs were seen as a necessary part of treatment, only 10% recommended that a drug be used without concurrent non-drug therapy, and non-drug treatments were seen as particularly important when the patient had shown improvement within a month (only 2% then recommended a drug alone), indicating recognition of the need for treatment to continue past the point when active psychotic symptoms are in remission.

Despite the lack of empirical evidence for the effectiveness of psychotherapy for patients with schizophrenia (Quality Assurance Project, 1984), more than half of the sample (58%) did recommend psychotherapy, either alone or in conjunction with family/social interventions. However, many of these recommendations were for Case 2 who, even initially, and especially when improved, showed insight into her condition; indeed, 98% recommended psychotherapy once she had improved. There is clearly a strong belief in the importance of individual psychotherapy amongst Australian psychiatrists. Moreover, for the other cases, the category of psychotherapy selected from the glossary was nearly always "supportive psychotherapy", which was defined as the use of "empathy, guidance, support and reasoning... to decrease anxiety in order that the patient may deal more effectively with real-life situations". Given this definition, it is just possible that psychiatrists intended some of their psychotherapy sessions to include counselling concerning the nature of schizophrenia, the goals of

treatment, the importance of drug therapy, and the need for the patient and family to establish independent social networks, which is emphasised by the family management approach of Falloon *et al* (1982). In this sense, there may be some overlap and/or common intention in recommendations for supportive psychotherapy and family counselling.

The treatment recommendations indicated that psychiatrists are aware of the evidence implicating the "expressed emotion" of the families of patients with schizophrenia in their relapse (e.g. Brown *et al*, 1972). Family/social interventions were the non-drug therapy of choice for both Cases 1 and 3, where the vignettes described family members as being variously critical, hostile, and overprotective—factors defining high expressed emotion. Moreover, recommendations for family/social treatment for Cases 1 and 3 increased when the patients had improved relative to initial presentation, indicating a recognition of the need to continue family intervention procedures, even when psychotic symptoms have improved, if relapse is to be prevented.

Conclusion

This survey revealed considerable consensus among practising psychiatrists in Australia as to the appropriate management of schizophrenia. Antipsychotic drugs, in combination with either supportive psychotherapy or family/social intervention procedures, were recommended by almost all psychiatrists who were prepared to treat the types of patients described in the questionnaire. There was less consensus concerning the appropriate treatment situation for patients suffering active symptoms, perhaps reflecting differences in the availability of outpatient or day patient services. Psychiatrists generally agreed that hospitalisation should be brief when improvements in symptomatology are evident.

Psychiatrists exhibited some reluctance to treat patients suffering from chronic schizophrenia. This is understandable in terms of the poor prognosis evident for such individuals. But the costs of schizophrenia to the community will remain high unless attention is devoted to increasing psychiatrists' confidence in their ability to manage such patients.

FROM CLINIC...

...TO COMMUNIT

CLOPIXOL®

zuclopenthixol dihydrochloride/zuclopenthixol decanoate

CLOPIXOL TABLETS contain zuclopenthixol dihydrochloride.

Indications Psychoses.

Dosage and Administration The usual initial dose is 20-30mg/day, increasing as necessary to a maximum of 150mg/day, in divided doses. The usual maintenance dose in chronic schizophrenia is 20-50mg/day in divided doses.

Children Not recommended.

Side-effects Extrapyramidal side-effects may occur and sometimes may require control by anti-Parkinson drugs.

Contraindications Acute alcohol, barbiturate or opiate poisoning. Intolerance to other neuroleptics. Pregnancy (relative). Use with caution in patients

with Parkinsonism, severe arteriosclerosis, senile confusion states, serious renal, hepatic or cardiovascular disease.

Overdosage Overdosage should be treated by gastric lavage.

Package quantities and NHS price (correct at time of printing) Bottles of 100 Clopixol Tablets 2mg £3.05, bottles of 100 Clopixol Tablets 10mg £7.50, bottles of 100 Clopixol Tablets 25mg £15.00. PL Nos 0458/0027, 0028, 0029. PA Nos 115/5/3, 4, 6.

CLOPIXOL INJECTION & CLOPIXOL CONC.

INJECTION contain zuclopenthixol decanoate 200mg/ml and 500mg/ml respectively in thin vegetable oil.

Indications Psychoses, especially schizophrenia.

Dosage and Administration 200-500mg every 2-4 weeks by deep intramuscular injection.

Children Not recommended.

Side-effects Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose reduction or anti-Parkinson treatment.

Contraindications Comatose states.

Precautions Caution in patients with advanced renal, hepatic, or cardiovascular disease, Parkinson's disease, pregnancy, car driving or machine operation.

Further Information Overdosage should be treated by (a) anticholinergic anti-Parkinson drugs if extrapyramidal symptoms occur (b) sedation (with benzodiazepines) in the unlikely event of agitation

or excitement (c) noradrenaline in saline intravenous drip if the patient is shocked.

Package quantities & NHS price (correct at time of printing) 10 x 200mg (1ml) ampoules £30.14, 1 x 200mg (10ml) vial £28.63, 5 x 500mg (1ml) ampoules £36.23. PL Nos 0458/0017, 0018, 0019. PA Nos 115/5/1, 5, 7.

A SCHIZOPHRENIC.

Adolf Wölfler spent 35 years in the Waldau Mental Hospital, Berne, suffering from schizophrenia. During that time he produced many drawings that have since gained widespread acclaim.

The picture below is one of a number that, we believe, give an insight into the schizophrenic mind and is reproduced with the kind permission of the Museum of Fine Art, Berne.

A SOLUTION.

Since the 1950s when Dr Paul Janssen and co-workers researched and developed the prototype butyrophenone haloperidol it has become widely established throughout the world as an effective antipsychotic. In 1982 Haldol* Decanoate was introduced to the UK as a depot neuroleptic with a consistent 4 week duration following a single deep intramuscular injection.

Dosage is from 50–100mg in mild symptomatology whereas severe schizophrenic symptoms are usually controlled with up to 300mg.

The schizophrenic patient can benefit from a flexible therapy with little incidence of sedation and a reduced requirement for antiparkinsonian medication, leaving him better able to participate in other forms of therapy.

Meeting the needs of the schizophrenic.

▼ **Presentation:** Straw coloured, viscous solution presented in 1ml brown glass ampoules equivalent to 100mg/ml haloperidol (as decanoate ester) and 1ml brown glass ampoules equivalent to 50mg/ml haloperidol (as decanoate ester) both in packs of 5. **Uses:** As a depot injectable form of haloperidol indicated for adults where long term maintenance treatment with a neuroleptic is required, for example in schizophrenia, other psychoses (especially paranoid) and other mental or behavioural problems where maintenance treatment is clearly indicated. **Side-effects, precautions, contra-indications:** Haloperidol is not recommended during lactation. **Use in Pregnancy:** The safety of haloperidol in human pregnancy has not been established. **Precautions:** Caution in liver disease, Parkinson's disease, phaeochromocytoma, thyrotoxicosis, epilepsy and conditions predisposing to epilepsy. Antagonism of adrenaline, guanethidine, phenindione, anti-Parkinson effects of levodopa, and impairment of metabolism of tricyclic anti-depressants have been reported. Haloperidol may increase the effects of CNS depressant drugs, and enhanced CNS effects when combined with methylidopa have been reported. Neurotoxic reactions to combined treatment with lithium and haloperidol have been reported. **Side Effects:** In common with all neuroleptics, the following side effects may be observed: sedation, extra-pyramidal symptoms, tardive dyskinesia, mental dullness, dizziness, headache, excitement, agitation, insomnia, hyperprolactinaemia, galactorrhoea, gynaecomastia, oligo- or amenorrhoea, hypotension. Gastro-intestinal symptoms and weight changes have been reported. Anti-Parkinson agents should only be given as required. The elderly are more susceptible to sedative/hypotensive effects. Rarely neuroleptic malignant syndrome has been reported. **Dosage:** Haldol* Decanoate provides one month's therapy following a single deep intra-muscular injection in the gluteal region. Dosage should be individually determined. As a guide: in mild symptomatology and in the elderly 50-100mg every 4 weeks; in moderate symptomatology 100-200mg every 4 weeks; in severe symptomatology 200-300mg or more every 4 weeks. **Product Licence No:** PL0242/0095, PL0242/0094 **Basic NHS Cost:** 100mg/ml: 1ml x 5 £24.00; 50mg/ml: 1ml x 5 £15.60 (correct at time of printing). Further information is available on request from Janssen Pharmaceutical Limited, Grove, Wantage, Oxon OX12 0DQ.

COMFORT MOOD DEPIXOL®

cis(Z)-flupenthixol
decanoate

CONC. 100 mg/ml

Depixol Injection and Depixol-Conc. Injection contains cis(Z)-flupenthixol decanoate, 20mg/ml and 100mg/ml respectively, in thin vegetable oil. **Indications** Psychoses, especially schizophrenia, particularly where there are associated features of withdrawal, inertia or apathy. **Dosage and Administration** By deep intramuscular injection, 1-2ml every 2-4 weeks, a maximum of 400mg weekly. **Children** Not recommended for children. **Side-Effects** Early (frequent) and late (rare) dyskinesias. Extrapyramidal effects sometimes require dose

reduction or anti-Parkinson drug treatment. **Contra-indications** Not recommended for overactive patients, or for those with Parkinsonism, severe arteriosclerosis, senile confusion, or advanced renal, hepatic, or cardiovascular disease, intolerance to other neuroleptics, pregnancy. **Package Quantities** Boxes of 10 x 20mg (1ml), 10 x 40mg (2ml), 10 x 100mg (1ml) ampoules; 5 x 20mg and 5 x 40mg syringes; 1 x 200mg (10ml) and 1 x 500mg (5ml) vials. **Further information** Overdosage should be treated: (a) By anti-

cholinergic anti-Parkinson drugs if extrapyramidal symptoms occur. (b) By sedation (with benzodiazepines) in the unlikely event of agitation or excitement. (c) By noradrenaline in saline intravenous drip if the patient is shocked. **Basic NHS Cost** 10 x 20mg amps £15.53; 10 x 40mg amps £25.99; 10 x 100mg amps £59.53; 5 x 20mg syringes £8.51; 5 x 40mg syringes £13.74; 200mg (10ml) vial £14.74; 500mg (5ml) vial £28.27. (Prices correct at time of printing.)

Post-Traumatic Stress Disorder Following Combat Exposure: Clinical Features and Psychopharmacological Treatment

A. BLEICH, B. SIEGEL, R. GARB and B. LERER

Post-traumatic stress disorder may follow combat stress or civilian psychological trauma. In 25 retrospectively studied patients, symptoms were severe in terms of number of DSM-III items fulfilled, chronicity, and severity of psychosocial disability. Antidepressants had good or moderate results in 67% of cases treated, but major tranquilisers were much less effective; response to drug treatment was not clearly related to somatisation symptoms, significant depression, or panic attacks. Pharmacotherapy appeared to have had a positive impact on psychotherapy in 70% of cases.

Post-traumatic stress disorder (PTSD)—a syndrome manifested months or years after the event by people who have been exposed to significant psychological trauma or stress—has been increasingly recognised as a public health problem of major proportions (Keane & Fairbank, 1983). It occurs most frequently in soldiers who have suffered acute combat reactions and thereafter develop chronic symptoms, which may result in severe social and occupational incapacitation (Figley & Leventman, 1980). PTSD may also occur among civilians who have been victims of natural catastrophes, criminal assaults, rape, industrial or traffic accidents, and terrorist attacks (Horowitz *et al*, 1980).

DSM-III (American Psychiatric Association, 1980) proposed an empirical clinical definition of the PTSD syndrome which is considerably influenced by the observations of Kardiner (1941). The characteristic symptoms involve re-experiencing the traumatic event, numbing of responsiveness to or reduced involvement with the external world, and a variety of autonomic, dysphoric, or cognitive symptoms. Beyond the core features of the syndrome, related to re-experiencing the original traumatic event, the clinical picture encompasses a number of symptoms of depression and anxiety. These include diminished interest in work and activity, sleep disturbance, guilt, difficulty in concentrating, hyper-alertness, and exaggerated startle responses. It is therefore highly plausible that psychopharmacological agents which are effective in alleviating symptoms of depression or anxiety might be clinically efficacious.

The empirical use of psychopharmacological agents by many clinicians treating PTSD patients has been only sporadically reported in the literature, and no controlled trials have been published. Hogben &

Cornfield (1981) reported five cases successfully treated with phenelzine (45–75 mg/day): traumatic dreams, flashbacks, startle reactions and violent outbursts were all improved, while the drug appeared to enhance psychotherapy by promoting abreaction. Walker (1982) also observed positive results with phenelzine in three PTSD patients, traumatic dreams and flashbacks being particularly improved, while Levenson *et al* (1982) reported therapeutic effects of phenelzine (75 mg/day) in a single case: spontaneous, intense preoccupation with the traumatic experience was attenuated. Shen & Park (1983) reported a single patient who responded to phenelzine (105 mg/day) but complained of sexual inhibition, which continued when he was switched to tranylcypromine. Burstein (1984) administered imipramine (50–350 mg/day) to ten patients with PTSD of recent onset, and observed significant improvement in forced recollections, sleep and dream disturbance, and flashbacks; the relatively quick onset of action suggested a specific mechanism of the drug on sleep and dreaming. A similar positive effect of imipramine on post-traumatic night terrors was reported by Marshall (1975).

The present report summarises the clinical features and response to a number of drugs, particularly antidepressants, of a group of 25 PTSD patients referred to the PTSD Unit of the Israel Defence Forces Psychiatry Division.

Method

Clinical notes of patients referred to the PTSD Unit were retrospectively reviewed. The diagnosis of PTSD, as made by the treating clinician, was re-evaluated on the basis of DSM-III criteria, and 25 patients fulfilling these criteria

were identified. Details of the clinical picture, drug treatments administered, and response to each of the treatment agents were summarised. The summaries were reviewed by three clinicians; two of these have been involved in treating a number of the patients, while the other had no direct familiarity with the clinical material. A consensus regarding response to treatment was established in each case. Retrospective judgments as to the interaction between drug treatments and concurrent psychotherapy were obtained by contacting the therapist involved, who was asked to assess, using his notes, whether drug treatment had had a significant effect on the therapy process and to define the nature of this impact.

Results

Population

The mean age of the 25 patients in the sample was 32 years (range 20–42); all were males, all were married, and all were on reserve duty at the time of the traumatic event. The average length of time intervening between the traumatic event and referral for treatment was 8 months (range 1–20). Seven patients had been treated in the field by psychiatric units for acute combat stress reaction, while 18 were new referrals to the Mental Health Division. In 17 cases the traumatic stressor was an event or series of events that occurred on the battlefield: sustained artillery barrage (nine cases), open combat (five cases), or wounds or fatalities sustained by others in the same unit (three cases). In four cases the stressor was an encounter with bodies of soldiers killed in action; in two cases it was acts of sabotage; and in two cases it was traffic accidents in the operational zone. At the time of referral none of the subjects were able to continue soldiering, and reserve duty had been temporarily deferred; all had significant impairment of occupational adjustment and general psychosocial functioning.

Clinical symptom picture

The clinical symptom picture at the time of referral of each patient was well documented in the notes. Table I summarises the frequency of each of the DSM-III items in the patient population, as well as additional clinical features not encompassed in the PTSD diagnostic criteria. Intrusion symptoms such as sleep disturbance, recollections of the event, traumatic dreams, and hyper-alertness or startle response were equally represented among the most frequent clinical features, along with avoidance symptoms such as decreased interest in significant activity, avoidance of activities that evoke recollections of the event, and detachment from others. The severity of the clinical syndrome in the group is indicated by the fact that 17 of the 25 patients fulfilled ten or more of the thirteen DSM-III criteria; seven patients fulfilled 7–9 of the criteria, and only one less than seven criteria. (The minimum number of criteria required for the DSM-III diagnosis is five.)

Of those clinical features not encompassed in the DSM-III criteria, somatic complaints were most commonly reported; these were usually multiple and ill-defined, although in some cases dominant symptoms were

TABLE I
Clinical symptom picture in 25 PTSD patients

<i>DSM-III items</i>	<i>No. of Patients</i>

Panic attacks	3
Alcoholism (suspected)	2

identified—most commonly headache (seven cases), impotence (five cases) and chest pain (four cases). In two cases with marked somatisation, the symptoms were sufficiently pronounced and numerous to satisfy DSM-III criteria for somatisation disorder. Significant depression was documented in six cases; all fulfilled DSM-III criteria for dysthymic disorder, but not for major depression. Three patients reported panic attacks which fulfilled DSM-III criteria for panic disorder. In two cases, alcoholism was suspected but could not be confirmed; there was no evidence for any other form of substance abuse in any of the patients.

Response to pharmacotherapy

Table II summarises the outcome of all the medication trials undertaken in the patient group which exceeded two weeks in length. In 17 cases there was only one trial per patient, in 4 cases two, and in 4 cases three. Except for one patient who had amitriptyline together with methotrimeprazine combined treatments were not used. Treatment outcomes were rated as good if there was substantial and sustained symptomatic improvement and enhanced psychosocial functioning, and as moderate if these parameters of improvement were incomplete or if effects were transient in spite of continued treatment.

There were a total of 28 antidepressant trials. Fourteen patients received amitriptyline; dosages averaged 139 mg/day, and the average length of treatment was 6.5 months.

TABLE II
Trials of psychopharmacological agents in 25 PTSD patients

Total (all drugs)	7	15	15	37

1. Combined in one patient with methotrimeprazine (50–75 mg/day).

Four patients had a good clinical response to amitriptyline, characterised by a complete alleviation of symptoms and significant improvement in psychosocial functioning, while another eight had moderately good responses, only one patient showed a poor response to amitriptyline. Doxepin was used in seven cases (mean dose 100 mg/day), with an average length of treatment of seven weeks; one patient manifested a good response and three a moderate one; while three others responded poorly to this treatment. Good responses were not obtained with any of the other anti-

depressants tried, although one subject had a moderate response to maprotilene (150 mg/day) and one a moderate response to clomipramine (150 mg/day). Neither of the two cases in whom phenelzine (30–45 mg/day) was tried showed any therapeutic benefit, although in one of these cases treatment was only for two weeks.

In those patients who responded well or moderately to antidepressants, the most prominent beneficial effects were on sleep, traumatic dreams, hyper-alertness, and startle response, memory, and concentration difficulties. One patient with enuresis reported disappearance of the symptom, along with overall general improvement, following doxepin treatment. Only two of the five patients with impotence had a therapeutic response, which was moderate in both cases. There was no clear relationship between presence or absence of somatisation, significant depression, or panic attacks and response to antidepressant treatment; neither did the severity of the syndrome, as indicated by chronicity and number of DSM-III items present at intake, appear to have any clear relationship to outcome.

Major tranquillisers were tried in eight patients. Dosages tended to be low (methotrimeprazine, 25–75 mg/day; thioridazine, 50–100 mg/day; sulpiride, 100–400 mg/day; fluphenazine, 5 mg/day). One patient had a good response to thioridazine (100 mg/day for two months), while one responded moderately well to thioridazine (50 mg/day for one month) and fluphenazine (5 mg/day for one month) at different times; neither patient was psychotic. The symptom picture in both these subjects was more activated, with prominent insomnia, nightmares, explosiveness, and hyper-vigilant symptoms. Major tranquillisers yielded a poor response in five of the eight cases. One patient was treated with chlordiazepoxide (40 mg/day for one month) with good results; his symptom picture resembled that of the two patients who responded moderately well to major tranquillisers.

Interaction of drug treatment and psychotherapy

Twenty of the patients were receiving psychotherapy at the time that drug treatments were instituted; in four cases, the prescribing doctor was himself the psychotherapist. In ten cases, the psychotherapy was defined as 'supportive', and in

TABLE III
Interaction of psychopharmacological treatment with psychotherapy

Type of interaction	Dynamic psychotherapy (n = 10)	Supportive psychotherapy (n = 10)
Positive interaction		
Increased motivation	8	6
Working-through enhanced	6	1
Negative interaction	0	1
No interaction	2	3

the rest there was a major emphasis on dynamic processes, uncovering, or abreaction.

Table III summarises the retrospective assessment by the psychotherapist of the perceived effect of concurrent drug treatment on psychotherapy response: there was felt to have been a positive interaction with psychotherapy in 14 of the 20 cases, with enhanced ability to 'work through' in 7. In all, motivation for treatment was believed to have been increased.

Discussion

In terms of severity of symptoms, chronicity, and psychosocial disability, the patients in this sample may be categorised as suffering from disabling post-traumatic syndromes. Their central clinical features closely resemble those described by Horowitz *et al* (1980), as well as those found in an epidemiological study of Israel combat veterans (Solomon, 1986). Recollections of the traumatic event were a major feature of the clinical picture, and were manifest both in the waking state and during sleep. However, relatively few patients reported suddenly acting or feeling as if the traumatic event was recurring (DSM-III, item B3), and there was a relatively low incidence of survivor guilt (DSM-III, item D2), although the unstructured interview techniques used may have reduced the emphasis on both these items, which in many cases require active elicitation. Symptoms indicative of psychic numbing and diminished responsiveness were as prominent as activation-type symptoms, with the exception of constricted affect (DSM-III, item C3). This item is less amenable to uniform clinical definition, which may explain its relatively lower frequency.

There was a major difference between the present subjects and Vietnam veterans with PTSD previously reported (Sierles *et al*, 1983; Yager *et al*, 1984): the virtual absence of alcoholism, drug abuse, and anti-social personality features. Twenty-one of the 25 veterans studied by Sierles *et al* (1983) met definitive diagnostic criteria for substance abuse, as opposed to 2 out of 25 subjects with suspected but unconfirmed alcoholism in the present sample. Antisocial personality was not diagnosed in any of our sample, and explosive, aggressive, or impulsive behaviour, while noted in some of the cases, were not major clinical problems. The combination of such behaviour traits with substance abuse has led to an almost stereotyped perception of the Vietnam veteran with PTSD, from whom our subjects differed markedly (Yager *et al*, 1984). Possible explanations for these differences are still purely speculative. It is, however, conceivable that the social environment of combat veterans with PTSD may strongly influence the symptomatic

expression of the syndrome beyond these core features common to patients from different cultures. Both alcoholism and drug abuse are considerably less prevalent in Israeli than in other societies, and this factor may be important. A further consideration is that public attitudes in Israel tend to be strongly supportive of the veteran, particularly one disabled in combat, and this may diminish any tendency towards alienation and anger.

Sierles *et al* (1983) emphasised the importance of considering other DSM-III diagnoses in patients with PTSD, and saw this approach as having important implications for treatment. However, other than substance abuse and anti-social personality, the incidence of additional diagnoses such as somatisation disorder, endogenous depression, and organic mental syndrome was relatively low in their sample. Dysthymic disorder was diagnosed in 24%, panic disorder in 12%, and somatisation disorder 8% of our patients; there did not appear to be a clear relationship between presence or absence of additional DSM-III diagnoses and response to drug treatment, though the small sample size and retrospective nature of the study preclude any definitive conclusions in this regard. This issue has important treatment implications, but its resolution will have to await prospective studies in larger groups of subjects.

Among the psychotropic drugs we administered, antidepressants yielded the best results. Amitriptyline was the most frequently used antidepressant and the most effective, but on the whole, responses to antidepressants tended to be partial or transient. Major tranquillisers had good or moderate results in only two of the eight patients to whom they were administered: their major effect appeared to be one of sedation, and in the absence of psychotic symptoms they cannot be regarded as indicated in PTSD patients. The single patient treated with a minor tranquilliser, chlordiazepoxide, reported a highly favourable response.

Previous studies with psychotropic agents in PTSD have also been open ones, and have focussed almost exclusively on tricyclic antidepressants and monoamine oxidase inhibitors. While antidepressants improved intrusion-type symptoms in our patients, the most prominent overall effect was in alleviation of insomnia and general sedation: this was also the clinical impression in the few patients who responded to major or minor tranquillisers. The possible specificity of tricyclic antidepressants and monoamine oxidase inhibitors for PTSD has important implications not only for treatment but for our understanding of the possible neurobiological underpinnings of the disorder (Van der Kolk *et al*, 1985).

The positive interaction observed between drug treatment and psychotherapy is also of considerable practical importance, since in a disorder such as PTSD, where psychological antecedents are compelling, there may be a reluctance on the part of psychotherapists to interpose drug treatment into the therapy process. Previous reports on the impact of drug treatment on psychotherapy in PTSD have been essentially positive, although the enhancement of abreactive processes noted by Hogben & Cornfield (1981) has not been emphasised by other authors (Levenson *et al*, 1982). The positive impact in the present sample appears to have been primarily mediated by improvements in sleep and overall

sedation, leading to a more positive and motivated approach to psychotherapy on the part of the patients, but in addition drug treatment was felt to have actively enhanced the psychotherapy process in terms of amenability to uncovering and working-through in a minority of subjects. Although impressionistic in nature, these findings suggest that drug treatment should be actively considered in planning treatment strategy.

Childhood Encopresis extended into Adult Life

The late prognosis of childhood encopresis is unclear: our literature reviews have failed to reveal any studies of it. Halpern (1977), discussing the effectiveness of treatment, states that this is difficult to evaluate "since encopresis is a self-limiting symptom". Bellman (1966) followed up 186 children with encopresis seen at two Stockholm clinics; their age range at follow-up was 6-19 years. She found a steady decline in encopresis from the age of six in boys and eight in girls. It disappeared by the age of 16, although there were two relapses—one at 17 and one at 19.

Encopresis can occur in psychotic adults and in those who are severely mentally handicapped (Bellman, 1966). The only reported case of an adult encopretic who did not fall into either of these groups was that of a 36 year-old 'infantile neurotic', who had been encopretic until the age of 13-14 and relapsed at 31, after he had "broken with his dominating mother and sister owing to the bad relations between them and his wife" (Gurewitsch, 1932).

As part of a community-based treatment programme for childhood encopresis, an approach was made through the local media to see if there were adult sufferers prepared to come forward. The replies came mostly from people who had become incontinent in old age and from the relatives of chronically incontinent, mentally handicapped adults. There were three possible exceptions to this, only one of whom finally accepted an offer to be seen.

Case Report

Mrs A, aged 40, still suffered from encopresis which had started when she was 10, after the sudden deaths of both her parents from cardiovascular disease. She was subsequently brought up by older siblings, most of whom died of cardiovascular disease at an early age. Her clear recollection of her symptoms starts at the age of 12; episodically from then, two or three times per year (mainly at moments of great anxiety) she would experience an urgent call to stool, and would pass a small amount of faeces into her clothes. She disliked school intensely, but has no recollection of being embarrassed by her soiling there. She married at the age of 18, without her husband being aware of this symptom, and it was not intrusive in the early years of their marriage. Two children were born, three and five years later. Subsequently, the symptom became more obtrusive, and led to increasing limitation in her social activity.

Relatively little treatment had been sought or offered. In an exacerbation eight years ago she was seen in a gastroenterology clinic, but it seems unlikely that she made her true history clear. Ordinary investigations did not suggest an organic cause for her disorder.

She was prompted to reply to our news article by her most recent exacerbation, which originated at a time when her husband experienced symptoms suggestive of serious cardiac disease and her son had just left home. At interview, she was apprehensive and unforthcoming; she gave the dreadful details of her family history with little expressed emotion, although somatic signs of anxiety and arousal were very evident. She regarded herself as sensitive and said she cried readily, though there were no somatic symptoms of depression. She experienced a mood of sadness and apprehension, which she thought might be either the cause of or an effect of her encopresis.

Her husband saw the symptoms as becoming more and more intrusive in social and domestic life and, although he was more placid since his cardiac disorder, he still felt irritated and controlled by his wife's unusual symptom.

Treatment was undertaken using a combination of behavioural and psychotherapeutic approaches; the former did not suit her personality structure, and five monthly meetings were arranged which were more psychotherapeutic. The focus was on grief work, and during the sessions she was able to weep over her childhood losses. Following these sessions, her husband reported that she had been radically transformed and was smarter, brighter, and happier. Her occasional encopresis persisted, but her mental state remained excellent over a period of a year.

Comment

A diagnosis of social phobia, as described by Marks (1969), could explain much of this history, the symptom of encopresis being serviceable in controlling the amount of exposure to social situations. However, encopresis does not seem to have been reported as a presenting symptom in social phobia. In addition, the urge to defecate, and occasional encopresis, can occur when the patient is at home alone and not overtly anxious. The symptoms of encopresis and social phobia thus appear to have arisen independently, but with the encopresis being used as an added justification for her social withdrawal. The stool passed is normal in consistency, and she is capable of retaining most of the faecal matter which is in the rectum: Kanner (1953) used the term 'partial encopresis' to describe this type of soiling pattern.

Parental death has been noted as a trigger to the onset of encopresis (Lehman, 1944), and regression to faecal incontinence following the sudden deaths of both parents could have been the mechanism which produced encopresis in this patient. Encopretic children have been described as inhibited, slow to warm up, and disliking school (McTaggart & Scott, 1959)—features which could be applied to our patient. Bawkin & Bawkin (1960) have described how encopretic children may remain clean for several months and then have a soiling episode.

Throughout her lifetime with this symptom the patient made little effort to obtain any advice or treatment, and her own management consisted of

avoiding situations where she could be humiliated by it. Holman *et al* (1982), in a follow-up study of children with encopresis who had been treated in a psychiatric in-patient unit, comment that the families rarely sought further help for the problem.

We wonder in how many other people encopresis has extended into adult life. Certainly, our experience of dealing with adults with late onset bowel incontinence who responded to us leads us to suppose that people will tolerate their symptoms for a long time rather than risk the humiliation of disclosure, although the media gave some help, editorial censorship precluded a wider exposure of our interest in helping these sufferers.

Changes in Mood, Appetite and Psychomotor Retardation in Depressed Patients Given ECT

Clinical experience suggests that treatment with electroconvulsive therapy (ECT) produces an early improvement in psychomotor retardation. Warnings have been given of the increased risk of suicide when ECT-treated patients recover motor activity before their depressed mood is alleviated (Slater & Roth, 1977).

In a recent study (Hibbert *et al*, 1984) the

Montgomery-Åsberg depression scale (MADS) was used to investigate changes in severity of a variety of depressive symptoms over time. It was found that whereas most of the items on the MADS co-varied closely, 'biological symptoms' such as reduced appetite and reduced sleep did not show a clear relationship to other depressive symptoms. This suggested that the MADS might be an appropriate instrument

with which to investigate the clinical impressions quoted above concerning the rates of recovery of different depressive symptoms during ECT.

Method and Results

Ten patients who fulfilled criteria for major depressive disorder (Spitzer *et al.*, 1978) were recruited for the study. Five were taking antidepressant drugs, but were judged by their consultant psychiatrist to be non-responders. All subjects received right-sided unilateral ECT from an Ectron Mark IV duopulse machine, with methohexitone, atropine and succinylcholine being given before ECT.

The subjects were rated using a modified version of the MADS, which has been fully described by Hibbert *et al.* (1984). The scale for psychomotor retardation (Åsberg *et al.*, 1973) was included. Interviews were carried out daily, before the start of ECT and throughout the course of treatment; no reference was made to the previous days' rating. For each item of the MADS the mean number of ECTs required to produce a 50% reduction in pretreatment rating score was calculated; differences between the means were assessed by the Mann-Whitney test.

Items on the MADS measuring reduced appetite and psychomotor retardation improved most quickly, at rates significantly greater than those for reported and apparent sadness and inability to feel ($P < 0.01$) (Fig 1). Inability to feel improved at a rate similar to that of reported and apparent sadness (Fig 1), confirming previous observations that the three symptoms of depressed mood co-vary over time (Hibbert *et al.*, 1984). There was no relationship on any item between initial MADS score and rate of improvement.

Discussion

Our findings suggest that motor retardation and reduced appetite are the earliest depressive features to improve during a course of ECT. However, because of the limitations of our study, the results must be regarded as preliminary. Firstly, the number of patients rated was small, and some were on psychotropic medication, which could have interacted with ECT. Secondly, the study was conducted openly and rater bias cannot be excluded. However, we did not predict the rapid improvement in appetite which followed ECT, although it is consistent with an earlier report by Russell (1960).

Our observations could be explained if reduced appetite and psychomotor retardation were more sensitive to change than other items in the MADS. However, data reported by Montgomery & Åsberg (1979) do not support this possibility. It is recognised that retardation is a relatively infrequent symptom (Montgomery & Åsberg, 1979), which is difficult to rate reliably (Hibbert *et al.*, 1984). In our study, however, seven of the ten patients had obvious psychomotor retardation which responded well to ECT.

FIG 1 Mean number of ECTs required to produce a 50% reduction in MADS score (RA = reduced appetite, PR = psychomotor retardation, IF = inability to feel, AS = apparent sadness, RS = reported sadness). The error bars on top of each column show the SEM.

We cannot exclude the possibility that the changes we have observed in the remission of different symptoms are part of the general pattern of recovery from depressive illness and might also be seen, for example, following treatment with antidepressant drugs. However, it is recognised that certain cases of depression, particularly those with retardation and failure to eat and drink, are sometimes resistant to antidepressant medication but respond quickly to ECT (Kendall, 1981; Paul *et al.*, 1981). In animals repeated electroconvulsive shock, but not tricyclic antidepressants, produces a rapid increase in dopamine-mediated behaviours (Cowen *et al.*, 1980). In man, there is also evidence for increased dopamine-mediated responses following ECT (Costain *et al.*, 1982). Since dopamine pathways may play an important role in locomotion and feeding (Ungerstedt, 1979), it is possible that the early effectiveness of ECT in treatment of retardation and poor appetite is mediated by change in brain dopamine mechanisms.

Clopenthiol Decanoate in the Management of Aggressive Mentally Handicapped Patients

The management of aggressive and disruptive behaviour in mentally handicapped patients is a severe problem, and it is widely accepted that drug therapy is only one component in the range of measures required for a comprehensive regime, although the use of depot phenothiazines is widespread (Craft & Schiff, 1980). The evidence for their therapeutic effectiveness in the mentally handicapped is usually empirical, and sometimes based on anecdotal evidence. Clopenthiol decanoate is widely used in the management of aggressive and disruptive behaviour in such patients, probably as a result of experience of the use of this drug in schizophrenic patients.

Carney & Rutherford (1981) reported a marked improvement in both aggressive and non-aggressive behaviour disorders in 20 chronic schizophrenic patients treated for 11 months with clopenthiol decanoate, while Visiwanathan & Rajhkowa (1982) stated that it was of undoubted value in the management of chronic in-patients, especially those with 'positive affective' symptoms such as hostility, aggression, suspiciousness, and irritability.

The only published report on the use of clopenthiol decanoate in mentally retarded patients (Yar-Khan, 1981) described a calming and behaviour-modifying effect in 15 subjects with

TABLE I
Behaviour and total number of recorded episodes of aggressive behaviour during the six months prior to starting and the six months on clopenthixol decanoate

Patient	Age	Sex	Six months before treatment	Behaviour and number (n) of recorded explosive incidents Six months after treatment	Final global rating
1	35	F	Shouts at staff, slams doors, antagonistic, jealous and impatient (n = 40)	Outbursts less severe, less frequent, participates in ward activities more (n = 1)	B ¹
2	33	F	Absconds, hits staff when apprehended, hits other patients indiscriminately (n = 31)	Less unpulskive but still absconds, able to concentrate in occupational therapy (n = 24)	S ¹
3	31	F	Runs to other wards, eats cigarette ends, agitated and aggressive to staff (n = 52)	Much calmer, long periods between aggressive outbursts (n = 11)	B
4	23	F	Emotionally unstable, attention seeking, aggressive if not cuddled, swears, spits, hits out at staff, resents male staff (n = 19)	Long periods of quiet and calm behaviour, only occasional outbursts (n = 11)	B
5	16	M	Spitful to staff and patients, unprovoked attacks (n = 47)	Less aggressive, shorter duration of aggressive episodes (n = 22)	B
6	20	M	Unprovoked attacks on patients and staff, bangs furniture, rips clothes, rolls down curtains, restless (n = 27)	Fewer aggressive episodes, patient more amiable between outbursts of aggression (n = 27)	B
7	21	M	Unprovoked attacks on patients and staff, destructive to furniture, clothing and windows (n = 18)	Outbursts less frequent, happier in-between outbursts (n = 9)	B
8	27	F	Bites fellow patients, excitable, overturns tables, and other furniture (n = 9)	No change in behaviour, more excited and disturbed (n = 15)	S
9	19	M	Restless, shouts, excitable, attacks and bites others, unprovoked outbursts of rage (n = 17)	Larger intervals between outbursts, enjoys other activities much more (n = 20)	B
10	32	M	Aggressive when depressed, agitated, wandering, incontinent, mood swings (n = 19)	Stable moods, no longer attacks other people, improved concentration and is more tolerant (n = 6)	B

¹B = better than before; S = same as before

aggressive, disruptive, agitated, and violent behaviour disorders. We report here preliminary observations of the clinical use of clopenthixol decanoate in the management of aggressive and disruptive mentally handicapped patients.

Method

Ten patients treated for behaviour disorders at the Stoke Park Group of Hospitals were included. This was the first group who received the drug there, because other types of medication had been unsuccessful in controlling their behaviour.

The Charge Nurse or Sister, in consultation with the ward staff, was asked to describe in detail any changes in patients' behaviour during the time of treatment with clopenthixol decanoate. A checklist questionnaire on the side-effects of the drug was also completed, and any side-effects were described in detail in the case notes. After six months, a final rating was made by the senior nurse as to whether the patient was better than before treatment, unchanged, or worse. The authors examined all the clinical notes made by the doctors and nursing staff during the period of treatment and for six months before treatment. Biographical information and details of medication both before and during treatment with clopenthixol were noted, along with the doses and side-effects of clopenthixol recorded in the case notes. The recorded incidents of explosive, aggressive outbursts were counted for the six month periods both before and after the start of treatment.

Results

Sample

The ten patients were all long-stay, ambulant, mentally handicapped in-patients, with an IQ range of 20-60, age range of 16-35, and mean age of 25.7. The sexes were equally represented. Three patients had epilepsy, and one was deaf. The behaviour disorders are shown in Table I. All patients had previously received drug treatments specifically aimed at controlling their aggressive behaviour. All had already been tried on oral phenothiazines, two patients had been given carbamazepine, and three had been treated with haloperidol, which was abandoned because of side-effects; lithium carbonate and fluspirilene had also been tried on two patients. However, none had been given depot phenothiazines. All other regular psychotropic medications were gradually withdrawn during the period of study.

Dosage and side-effects

The two psychiatrists used different starting doses, one used the manufacturer's recommended starting dose of 100 mg i.m., while the other began with 50 mg i.m. All three patients who received the recommended adult starting dose of 100 mg developed extrapyramidal side-effects (tremor, rigidity, and dystonia) in the first two weeks after starting treatment, which led to an initial increase in the number of episodes of aggressive behaviour. When these side-effects were treated with anti-parkinsonian drugs, the patients'

behaviour settled. None of the patients who received the smaller test dose showed any extrapyramidal side-effects. The maintenance doses were gradually built up, and at the end of the study the maximum weekly maintenance dose being given and tolerated was 300 mg.

The range of other side-effects observed included dry mouth (five patients) and a significant gain in weight (four patients, all females).

Therapeutic effectiveness

Eight patients were rated as being better than before, i.e. much calmer and more receptive to other therapeutic interventions such as behaviour modification and participation in ward activities. Six had a significant reduction in the number of recorded incidents of explosive aggressive outbursts during the treatment period (Table I). Two patients, both females, were rated the same as before treatment: one was an epileptic who became more unsettled during treatment, and another was a lonely and withdrawn girl who only became periodically aggressive when asked to join in activities of the ward. Both became so excitable and hyperactive during treatment that clopenthixol had to be stopped. It was generally felt that the patients who responded well to clopenthixol were those whose episodes of aggression were seen against a background of a chronic state of high arousal.

Discussion

Our observations indicate that clopenthixol decanoate may be useful in reducing aggressive and disruptive behaviour in mentally handicapped adults. This confirms the clinical impression of Yar-Khan (1981), who appealed for further study, and the need for a properly conducted controlled trial is clearly established. However, future studies will need to have an operational definition of what constitutes 'aggressive behaviour' and to standardise the methods of selection and assessment of patients. The nurses' assessments in this study were open to bias and not standardised, but it was interesting to see a dramatic reduction in the number of recorded episodes of aggressive behaviour during treatment with clopenthixol decanoate.

Any therapeutic response observed in a drug trial may be due to 'specific' or 'non-specific' effects of the treatment (Shepherd, 1975), so careful control of all the factors which can contribute to the observed response is essential. This calls for a careful record of any concurrent medication administered, and of any changes in the environment or life events experienced by each subject, because all these factors can contribute to the observed outcome. For instance, most patients who responded well to clopenthixol decanoate in these preliminary observations had their ward environments renovated and upgraded during

the period of treatment. This experience alone could have non-specifically contributed to improved behaviour. A prospective controlled trial, involving subjects selected according to specified criteria, would be the most appropriate method of study.

Paranoid Reaction and Underlying Thyrotoxicosis

Woodbury (1918) described the manifestations of Graves' disease as fatigue, irritability, intolerance to heat, fine tremor, restlessness, insomnia, excitability, labile emotional disposition, nervousness, weight loss, palpitations, doubts, and fears. Similarly, Sachar (1975) included nervousness (manifested as apprehension, restlessness, and inability to concentrate), marked emotional lability, and hyperkinesia as the most common presenting symptoms. That fatigue, irritability, emotional instability, and excitability are all common features of the hyperthyroid state, as are episodes of severe and often disabling anxiety, is therefore, accepted. On the other hand, no clear picture exists concerning any fixed constellation

of psychotic symptoms or progression of psychiatric disease. The psychiatric presentations vary from a delirious state to periods of hyperexcitability simulating mania that alternate with periods of exhaustion and depression. Greer & Parsons (1968) reported that some patients do, however, develop a clear schizophrenia-like picture, closely associated with the course of hyperthyroidism, with prominent paranoid symptoms and no pre-morbid history of psychosis.

We present a case of paranoid reaction in association with hyperthyroidism, which responded to neuroleptic treatment and the restoration of the euthyroid state.

Case History

A 43 year-old woman had been unwell for five days before admission: she had become increasingly restless, irritable, and unable to concentrate or sit still, according to her 19 year-old daughter (an unmarried mother living with her parents). The patient kept telling the daughter that there were problems with her marriage, and also became very critical about the way in which her daughter dealt with the baby. The patient became so agitated that she was taken to her general practitioner; there, she became convinced that her husband was hiding from her in the surgery and that she could hear his voice in the distance, talking about her. She was restless and agitated, but co-operative. She seemed apprehensive, and expressed paranoid ideas about her husband. She complained of feeling tired and unable to sleep; her sensorium was clear, but she lacked insight into her condition.

There was no evidence of social or psychiatric problems prior to this episode, but the patient described herself as a very "worrying type" of person, who tended to 'bottle up' her feelings. The patient's mother had a thyroidectomy for thyrotoxicosis, but there was no family history of psychiatric illness. On physical examination, she had a smooth enlarged goitre with a bruit. She had slight tremor of the hands, exophthalmos with lid-lag, and a resting pulse of 105/min. Her laboratory results indicated elevated thyroid indices, with T_3 uptake of 39.2% (normal range 25–35%), thyroxine 289 nmol/l (normal range 55–145 nmol/l), free thyroxine index 107 (normal range 18–46). Consultation with a specialist in endocrinology confirmed the diagnosis of hyperthyroidism. Treatment with carbimazole (15 mg t.d.s.), propranolol (20 mg t.d.s.) and chlorpromazine (50 mg t.d.s.) was started. The paranoid symptoms resolved dramatically after two months, she was euthyroid within four months, and on review after nine months she still remained symptom-free on reduced dosages of carbimazole (10 mg), propranolol (20 mg b.d.), and chlorpromazine (50 mg once/day).

Discussion

This case serves as a reminder of psychiatric presentations of thyrotoxicosis, and highlights its responsiveness to phenothiazine treatment. However, the mechanism by which hyperthyroidism causes psychiatric disorder is still not clear. Various views have been put forward on pathogenesis, and claims have been made that the behavioural, neurotic, and psychotic manifestations of hyperthyroidism are related more to the biochemical abnormalities associated with the disease than they are to the patients' previous personality. Ettigi & Brown (1978) stated that the psychiatric disorder is probably not caused by the cellular hypermetabolic state alone, since hyperthyroidism is also associated with an increased sensitivity of central nervous system neurotransmitter receptors to catecholamines, depressed monoamine oxidase activity levels, and increased norepinephrine turnover rates. The acute paranoid reaction in our case appears to have been associated with hyperthyroidism, but the patient's anxiety-prone personality may also have been a contributory factor. We assume that a combination of metabolic, biochemical, pre-morbid personality, and emotional factors were implicated in the causation of this psychiatric disorder. Our observation confirms the suggestion by Burch & Messerey (1978) that if a hyperthyroid patient developed psychotic symptoms, this can often be controlled with chlorpromazine.

Multiple Pathology in a Mentally Handicapped Individual

A doctor is trained, perhaps over-trained, to try to limit his diagnosis to a single disease process or entity. This may lead on occasion to a somewhat blinkered approach to the management of patients.

The following case illustrates multiple and concomitant pathology in a single individual.

Case Report

Miss JF now 40, was admitted in 1951, aged seven to Leytonstone House, which was then a typical, traditional, custodial institution for the mentally handicapped. She was a first child. Her mother was 29 at the time of her birth, and had suffered from hyperemesis gravidarum during pregnancy; she was admitted to hospital soon after going into labour, which lasted four days. JF developed petit mal attacks at the age of three months, when she had already developed whooping cough. Her developmental milestones during the first nine months were normal, although she was described by both parents as difficult, moody, and fretful. She babbled at ten months, but her speech never developed beyond a few words. By 18 months she was dry and clean, but during her moody periods she would smear her faeces—a habit which continued till she was seven.

The parents noticed that from the age of two she was fond of popular tunes and was often heard humming and babbling them; they regularly played music to quieten her down. Both parents vividly recollected that their daughter never braced herself on being taken up into their arms, during her second and third years she was emotionally unresponsive to their attentions, including cuddling, and became upset by the slightest digression from her daily routine. They also noticed that although she occasionally bit her hands, she never seemed to feel pain, even when she injured herself, to the extent sometimes of producing cuts which bled, this habit still recurs during periods of frustration. On admission, she was diagnosed an 'imbecile'; psychological testing placed her IQ at 30 (Terman Merrill and Merrill Palmer scale). She was at that time restless and easily distracted. Her self-mutilating tendencies continued, as did her aggression to others. At the age of eight she developed grand mal epilepsy, and these seizures still occur at an average rate of one per month.

At the age of 30 she developed a depressive illness marked by tearfulness, social withdrawal, loss of appetite, and

disturbed sleep. She responded well to amitriptyline (75 mg nocte), but soon after her recovery (which took six weeks) became overactive—dancing, humming, and frequently biting other people. Amitriptyline was stopped and chlorpromazine (100 mgs t.d.s.) was given for three months, but there was no significant change. During the fourth month, however, her hypomania subsided.

Two years later she again relapsed into a state of excitement and aggressive behaviour and was again put on chlorpromazine. She recovered from this episode after about five months. Six years later she developed a severe depression which responded to dothiepin (75 mg nocte). Again, her recovery was followed by an episode of elated mood with disruptive and aggressive behaviour, which this time responded to haloperidol (10 mgs t.d.s.).

After a diagnosis of manic-depressive psychosis, she was started on lithium carbonate (800 mg nocte). Since this regime was commenced, she has had over three years free of affective disorder, and has become much more manageable. In February 1984, an EEG showed "marked abnormal record, slow sharp waves over the temporal region with right sided emphasis".

Comments

Boullin *et al* (1970) stated that infantile autism could be due to a genetic defect causing disturbance in tryptophan metabolism, while Post (1980) has pointed out that manic-depressive illness may be due to a single dominant gene with incomplete penetration, leading to a disturbance in the metabolism of tryptophan. When infantile autism and manic depressive illness occur together, it is reasonable to assume that the same gene may be responsible for both, since the same metabolic error may be shared. In this particular case, epilepsy may indicate an organic factor which could be a component of infantile autism. The possible relevance of abnormal tryptophan metabolism to the above syndromes should be considered in future research strategies.

Books Reconsidered

Sanity, Madness and the Family: R. D. Laing and A. Esterson

In this series, Andrew Smith (1982) reconsidered R. D. Laing's *The Divided Self* (1960). In his sensitive, wideranging review of Laing's first book, he added to the growing weight of opinion in some psychiatric circles that it is a major though idiosyncratic contribution to our understanding of schizophrenic psychopathology. It is after all on the Royal College of Psychiatrist's current psychotherapy reading list. *Sanity, Madness and the Family*, first published in 1964, and the work which accompanied it, remains outside mainstream psychiatry yet I will argue has had an impact exceeding that of *The Divided Self* on today's practice.

The first Tavistock publication was subtitled, *Volume 1, Families of Schizophrenics*, with the implication that further volumes would deal with families of other psychiatric patients or normals. The preface to the second Penguin edition (1970) explains that on reflection the use of a control group would not help the authors answer *their* question, namely, "are the experience and behaviour that psychiatrists take as symptoms and signs of schizophrenia more socially intelligible than has come to be supposed?" (p.12). The term "intelligible" replaces "comprehensible" as in *The Divided Self*—and is crucial. It is a term borrowed from Sartre meaning the making sense of that which is between "what is going on (process) and who is doing what (praxis)" (p.22). We will come back to whether or not this question was answered or indeed whether it was a useful question to ask in the first place. Pausing to examine the preface itself, reveals that it is its stridency and vituperation which incensed reviewers and perhaps discouraged them from reading further. The late Eliot Slater (1971) reviewed the 2nd edition for this *Journal* (the first was not submitted) and stated that "to formulate this question involves a hypothesis regarding schizophrenia" despite the authors disclaiming any intention to propose such a hypothesis, indeed the word schizophrenia is isolated in parentheses hoping perhaps it would wither and die. Slater's answer to the authors' question was an emphatic "no" and he went on to describe the whole enterprise as "irrelevant" and "disingenuous". Disingenuous it may have looked, being bereft of reliable measures, controls and unbiased sampling, but irrelevant it certainly

was not. In a review of *The Self and Others* (Laing, 1969) Professor J. K. Wing (1971), though describing Laing's observations on families of schizophrenics as "subjective and partisan" goes on to confirm his importance to psychiatry if only as a curious social phenomenon.

R. D. Laing and Aaron Esterson, a contemporary from Glasgow University, set about elucidating the context of behaviours and experiences in order to make schizophrenia intelligible, comprehensible, meaningful and understandable. Following on from earlier work, it challenges the notion that the quintessence of schizophrenia is its un-understandability (Jaspers, 1963). This meaningfulness is seen as residing in the family "nexus" with the implication that "the schizophrenia" somehow exists only within the shared experience of a family "system", a concept derived from cybernetics and sociology and brought to bear upon families by the influential Bateson group (Bateson *et al.*, 1956). Laing and Esterson did this by exhaustive interviews, often totalling 50 hours, with 11 female schizophrenic patients both when well and psychotic, alone and with family members in all combinations. So rich in detail were their observations that one family case history, the Danzigs, was expanded into a book (Esterson, 1970). This appreciation for the subtle nuances of communication, verbal and non-verbal, and the realization that the interaction between a patient and his or her family may be infinitely more revealing than individual interviews was ahead of its time. Such concern for detail and recording belies the charge that Laing and co-workers were less than serious students of interpersonal relationships. The question of whether this effort answered their hypothesis is largely in the eye of the beholder. The data presented is of necessity highly selective. For example, does the repeated invalidation of patient Maya Abbott's feelings/beliefs/desires by her parents such as "you don't really think that," explain her ideas that her thoughts are being taken away or controlled? Does the fact that a mother listens to her daughter's telephone calls render intelligible her delusion that people listen to her telephone calls? Is Clare Church's impoverished affect explicable in the light of her parents' inconsistent and contradictory attitudes to

Clare's affection for others? For most psychiatrists, the provision of context is insufficient to explain the form that a patient's experiences take, which is recognisable as pathological. Indeed the authors acknowledge that to understand fully Lucie Blairs' "phenomenology" they have to invoke "internalization and re-projection" (p.74). The meaning which Laing and Esterson ascribe to "content" is ingenious and in itself a valuable contribution since many of the phenomena they examine are undoubtedly schizophrenic, frequently Schneiderian symptoms. If we allow a qualified "yes" to their question it still leaves many of ours, perhaps more important, untouched. Contemporary researchers were left to discover whether families of schizophrenics are more disturbed than families of other psychiatric patients (see Hirsch & Leff, 1975, Rund, 1986). Does this reflect a shared genetic constitution (see Wender, 1977) or the non-specific effects on parents of having a disturbed child (see Wynne *et al*, 1976)?

The anti-intuitive finding that schizophrenics discharged from hospital fared worse when they returned to their parents (Brown *et al*, 1962) led to a substantial body of influential work from the Institute of Psychiatry reviewed recently by Hooley (1985). The techniques used for inferring family interaction from interviews with one or other parent were crude in comparison to Laing and Esterson's. The highly sensitive dissection of intra-familial communication cannot easily be rated reliably so cannot be taken into account when measuring expressed emotion (EE). This work has been extended by psychologist, Michael Goldstein and his team who have used EE and other measures called communication deviance and affective style to examine interaction directly and in more detail. If it were possible to rate Laing and Esterson's recordings and transcripts they would almost certainly be found to be heavy with all these parameters. It seems that the authors were grappling with the same abnormalities that have provided others with a venerable area of research. Their mistake was to claim more for their studies than the methodology allowed. For instance, their statement that all families of schizophrenics are seriously disturbed is clearly an overstatement which can be explained by the fact that their subjects were chronic and frequently relapsing and so were likely to come from high EE families. By sticking to the issue of relapse, workers at the Institute of Psychiatry have avoided such accusations. The Goldstein group have been more ambitious and have tried to address aetiological issues in a family study follow-up of disturbed adolescents (Goldstein, 1985). Twenty years after Laing, and with a host of collaborators, the same questions remain substantially unanswered.

One area in which *Sanity, Madness and the Family* has been particularly influential is family therapy in that the book linked schizophrenia with family pathology in a way that was vivid and convincing, especially to those practitioners without medical training. This was probably unintentional as the authors object to the notion of "family pathology" as strongly as they do to neuropathology arguing that this "biological analogy" has no place in a "social phenomenological" perspective. This major theoretical difference does little to disguise the similarity between the processes they describe and those described by family therapists such as enmeshment, disqualification, collusion and so on. Family therapy is an anathema to Laing and his colleagues as is physical treatment. David Cooper (1967), quipped that "curing" is something one does to bacon and not people called schizophrenic. For Laing and Cooper, the only "treatment" was to get the patient out of the home and in to an environment free from coercion. This was based presumably on the assumption that patterns of interaction cannot be changed, a view certainly not shared by family therapists (e.g. Minuchin, 1974; Falloon *et al*, 1985). Simply reducing face to face contact may be protective (Leff *et al*, 1982). The experimental ward, Villa 21, at Shenley Hospital in which Cooper managed schizophrenic patients may have served this purpose among others. Patients could come voluntarily and refuse treatment if they wished. They had a close one-to-one relationship with a staff member from a multi-disciplinary team. The ward was run democratically with patients holding communal responsibility. The doctor relinquished his white coat. This "daring" set-up does not sound the least revolutionary now. Indeed the District Services Centre at the Maudsley Hospital and many other places like it, provides continuing care for chronic psychiatric patients along very similar lines. The efficacy of this sort of programme was assessed in comparison to the standard treatment of the time and published in a little known paper in the *British Medical Journal* (Esterson *et al*, 1965). The authors could be said to be advocates of asylum in its broadest sense (as in the Philadelphia Association) and not community psychiatry or, for that matter, anti-psychiatry which seeks to destroy all such institutions and which Laing decries (McGinley & David, 1985).

The most trenchant accusation made of Laing and *Sanity, Madness and the Family*, is the crime of parent blaming. It is difficult to find an explicit example of this in any of Laing's writings. Nevertheless, whether it was his intention or not, his tone and posture at times leads the reader inevitably to this conclusion. There can be no victim without a

victimizer. The review from *New Society* quoted on the cover of the Penguin edition talks unabashed of the "ugly sight of children being brainwashed by parents". Families too have inferred an attack as shown by many heart-felt essays collected by the National Schizophrenia Fellowship (1974). It is not enough, *not* to blame them; families must be supported and actively encouraged (Berkowitz *et al*, 1981). In the terminology of family therapy, their attitudes and actions must be "positively connoted" if any change is sought and a therapeutic alliance is to be maintained.

In conclusion, *Sanity, Madness and the Family* may be judged more favourably in hindsight than it was when first published. In an effort to give method to extreme forms of madness, it has helped to deflect the psychiatrist's microscope towards examining social interaction in a naturalistic way rather than in

the sterile confines of the laboratory. It reminded us that "Those psychiatrists who are not prepared to get to know what goes on outside their clinics and hospitals simply do not know what goes on" (p.13). It has encouraged family approaches even in psychotic disorders and the growth of family therapy, unwittingly perhaps. Unfortunately, it probably alienated some families in the process. By virtue of its appeal to public and hence patient opinion, and influence on non-medical and some medical staff, it has contributed to an atmosphere whereby less formal, more eclectic care for severely disturbed psychiatric patients could flourish.

Deficits of Chronic Schizophrenia in Relation to Long-term Hospitalisation

Sir: Mathai & Gobinath's study (*Journal*, May 1986, 148, 509-516) casts further doubt on the role of 'institutionalisation' in determining the course of chronic schizophrenia. We have argued (Abrahamson & Brenner, 1978; Abrahamson, 1983) that the positive correlation between length of stay and negative handicaps characteristic of previous studies was a reflection of the inadequacy of a cross-sectional approach. A cohort of patients with negative handicaps which persisted largely unchanged through hospital courses of 30 years or more was mainly responsible for the positive correlations we obtained retrospectively, which were strikingly similar in pattern to those obtained by Wing & Brown (1975).

It seems possible that Mathai & Gobinath have avoided this particular pit-fall because few such patients now exist in their long-stay populations or, more probably, because they were screened out by the diagnostic and exclusion criteria. It is notable that none of the patients were aged over 55 years and that only 8.8% of the NIMHANS and 18% of the MH long-stay populations were included. Whilst avoiding one source of bias others may have been introduced by the exclusion process, or submerged in the cross-sectional analyses. We found it revealing to relate the scores on disability scales to length of stay year-by-year rather than to longer time spans. In addition, despite their limitations, case-note studies provided an invaluable longitudinal dimension, the importance of which is underlined by prospective studies of long-term courses (Bleuler, 1978; Harding & Strauss, 1985). The numbers in Mathai & Gobinath's groups are sufficiently small for detailed

case-note studies to be feasible for all the patients included and samples of those excluded.

The main impression from the Goodmayes study, which has been reinforced by continuing experience with some of the patients concerned, is of the individual consistency of courses. A longitudinal framework is therefore essential to do justice to social influences, which appear to operate within narrow, perhaps biologically determined, constraints over a very long time course. A much more complex explanation than either a disease process or a social model alone provides is likely to be required for the re-evaluation of 'institutionalisation'.

The Northwick Park Study of First Episodes of Schizophrenia

Sir: Hidden away in the four papers on first episodes of schizophrenia from Northwick Park (*Journal*, February 1986, 148, 115-143) is information of interest to psychogeriatricians. First, the inclusion of patients "aged between 15 and 70 years, with a first psychotic illness, not unequivocally affective", would suggest that British psychiatrists accept that schizophrenia can develop for the first time in patients over the age of 40 or 45. Second, Table I (page 116) shows that three patients were excluded as being outside the age range. Were any of these over the age of 70? Third, Table I (page 129) shows that 37 of 253 (14.6%) patients were aged 40 or over on admission. The Table shows the expected excess of males over females for all ages, but does this relationship hold for the older age groups? Fourth, Table I

(page 129) also shows that there was one patient aged 60–65 who was trial eligible, but not a trial entrant. Table I, (pages 122–123) shows that randomisation was applied to patients only between ages 15 and 59. Why? Does this mean the researchers were reluctant to diagnose schizophrenia in a patient aged 60 or more?

Drs Johnstone, Macmillan and Crow Reply

Sir: We limited our age range to 15–70 years largely for practical reasons. Our collaborators like ourselves generally only see patients within that range and furthermore a study which involved a 2-year follow up while the patients continued on drug regimes with stated minimum doses would have been associated with additional difficulties in the very young and the elderly. The three patients excluded from the trial on the grounds of age consisted of a 14 year old male, a 71 year old female, and a 73 year old female. The 37 patients aged 40 or over on admission consisted of 22 females and 15 males. The trial eligible patient aged between 60 and 65 who was not a trial entrant was a 65 year old lady who did not wish to participate in the trial. She would have been very welcome to do so but her refusal meant that there was no-one over the age of 60 to be included in the randomisation process.

Alcohol Related Problems in Ethnic Minorities

Sir: We read with interest Dr King's paper on at-risk drinking among general practice attenders (*Journal*, May 1986, 148, 533–540). We were interested to find that there were significantly more Irish and Scots among the at-risk drinkers but were surprised to note that no Asians seemed to fall into the at-risk group. This was in spite of the fact that 28% of the screened population had a country of birth outside the United Kingdom. We have recently looked at the differences in morbidity patterns between Asians and non-Asians with a diagnosis of alcoholic liver disease at the Royal Free Hospital (Banerjee *et al*, 1986). Our results showed that of the 852 biopsies performed showing alcoholic liver disease between January 1978 and November 1984, 58 (6.8%) were from Asian patients. This is a higher percentage than one

would expect when corrected for the percentage of Asians in the population.

Previous studies have suggested that there are differences in alcohol sensitivity between different ethnic groups (Chan, 1986; Ewing *et al*, 1974). In addition, it has also been shown that drinking patterns vary between different ethnic groups (Caetano, 1984). We suggest, therefore, that Asians are a high-risk group for alcohol related problems (Balaharan *et al*, 1984) and the apparent low incidence of alcohol related problems in surveys may be due to socio-cultural taboos which result in under-referral to the patient's local general practitioner.

Hypomania Following Cognitive Therapy

Sir: We enjoyed reading the letter from Drs Hughes & McKane (*Journal*, March 1986, 148, 344). They suggest that the patient we describe is typical of a bipolar affective disorder developing in middle life. However, continued assessments of this patient for two years after involvement in the research study have shown no further episodes of affective disturbance. This might be expected in a patient with an initial diagnosis of dysthymia, which in DSM-III terms is a low grade depressive disturbance that is rarely associated with bipolar affective disorder. We were also excited by their hypothesis that the filling in of numerous questionnaires may induce mania. An examination of the data from our study reveals 120 patient-years of questionnaire administration but no other case of mania has been found. Reluctantly, therefore, we had to abandon this hypothesis. We are left, therefore, with an isolated case of mania manifested towards the end of a programme of cognitive therapy. Although no case report proves a hypothesis, it is reasonable to conclude that the

temporal relationship between treatment and the onset of manic symptoms was not entirely coincidental and therefore worthy of report.

Radioreceptor Assay of Serum Neuroleptic Concentrations in Psychiatric Patients

Sir: We read with interest the report by Kraska *et al*, (*Journal*, February 1986, **148**, 187-193), concerning the usefulness of radioreceptor assays for the measurement of plasma neuroleptic concentrations. We have been assessing the usefulness of a similar assay based on a lyophilised calf caudate preparation and ³H-labelled spiperone ligand, which is available from Wellcome Diagnostics as a 200 assay kit (Lader, 1980). We have found this assay simple to use and reproducible, requiring only 0.2 ml of plasma for each duplicate analysis. The assay has been found to be linear between 15 and 1000 neuroleptic units per litre (1 NU/l equivalent to 1 nmol/l haloperidol).

In contrast to Kraska *et al*, who investigated patients on long-term therapy, we are investigating the application of this assay to the management of acute schizophrenia and have so far studied nine patients. All our patients were previously untreated, fitted the RDC criteria for schizophrenia (Spitzer *et al*, 1975), and were treated with haloperidol in doses of between 1.5 and 60 mg per day according to clinical judgement. No other neuroleptic or psychotropic medication was prescribed. We found a significant linear relationship between daily dose of haloperidol and plasma dopamine receptor binding activity ($n=11$, $r=0.76$) similar to that reported by Kraska *et al*. In three patients who were intensively investigated over a 4-6 week period there was a marked clinical improvement, as assessed on the CPRS rating scale (Åsberg *et al*, 1978). We found a direct relationship between dopamine receptor binding activity, dose and clinical improvement. However, due to the small number of patients, statistical significance could not be reached. This improvement was obtained on doses of between 9 and 20 mg/day haloperidol, which achieved plasma neuroleptic concentrations of 14-48 NU/l.

Extrapyramidal side-effects, as assessed using the Simpson Rating Scale (Simpson & Angus, 1970), were completely unrelated either to dose or to plasma neuroleptic concentrations. This poor relationship between plasma neuroleptic activity and extra-pyramidal side-effects was confirmed in six additional patients. These findings underline the conclusion reached by Kraska *et al*, that for chronic schizophrenics there was no simple relationship between plasma neuroleptic concentrations and side-effects. It is interesting that side-effects seem to be so poorly related to

total plasma neuroleptic dopamine blocking "activity" as measured in a radioreceptor assay. This may be because the assay measures only the total plasma concentration of "active" drug *in vitro* rather than reflecting dopamine blocking activity in brain *in vivo*. Another major problem with the use of this technique is that dopamine receptor binding activity may differ from one neuroleptic to another by several orders of magnitude despite equivalent clinical effects. The results are therefore meaningless if the patient is on more than one neuroleptic drug at the same time, a situation which pertains frequently in clinical practice.

Although a number of early reports indicated that radioreceptor assays showed promise, more recent work has been equivocal (Dahl, 1986). It is likely that such assays offer very little advantage over alternative techniques, e.g., gas and liquid chromatography which are capable of measuring parent drugs as well as metabolites which may have activities on different neurotransmitter systems. Much more work is required before dopamine blocking radioreceptor assays can offer any useful information in the management of schizophrenic patients.

Neuroleptic Malignant Syndrome

Sir: In their recent review of the neuroleptic malignant syndrome (NMS) Drs Abbott & Loizon (*Journal*, January 1986, **148**, 47-51) recommended sodium dantrolene and bromocriptine as the best treatment options for this syndrome. We wish to suggest the possible use of electroconvulsive treatment (ECT) in NMS in addition to these treatment modalities.

Case Report: We recently treated a patient who presented a NMS which improved with ECT. This 23 year old male schizophrenic patient developed NMS on the fourth day

of his treatment with intramuscular chlorpromazine (200 mg/day). The clinical features and laboratory results were typical for NMS, including extreme muscle rigidity, severe dysautonomic disturbances, and laboratory findings of rhabdomyolysis. In spite of the discontinuation of chlorpromazine the patient's condition deteriorated over the following week. On the seventh day of NMS a bilateral modified ECT was administered which was followed by a dramatic improvement in hyperpyrexia, diaphoresis and level of consciousness. The patient received a course of five ECT treatments within 2 days. When ECT was stopped fever and stupor recurred. Four further sessions of ECT were administered resulting in a complete recovery.

A survey of the literature revealed four case reports of successful treatment of NMS by ECT, (Powers *et al*, 1976; Jesse & Andersen, 1983; Lazarus, 1986). In another patient (Regestein *et al*, 1977) ECT during NMS was followed by permanent brain damage. This patient, however, had suffered from cardiac arrhythmia before ECT, and developed ventricular fibrillation followed by brain anoxia during the ECT. The disastrous outcome did not result, therefore, from a direct action of ECT on the brain. Besides specific contra-indications for ECT, this procedure seems an effective treatment for NMS. The ability of ECT to increase post-synaptic receptors' sensitivity for dopamine (Lerer & Balmaker, 1982) might explain its beneficial effect in NMS. This explanatory model is in line with the aetiological role attributed to an acute reduction in CNS dopamine activity in NMS.

Sir: We were interested to read the review on the neuroleptic malignant syndrome by Abbott and Loizou (*Journal*, January 1986, **148**, 47-51). Whilst the quotation from Baastup and colleagues (1976)

accurately reflects their finding that none of the 425 patients in their review treated with both lithium carbonate and haloperidol developed the neuroleptic malignant syndrome, we were intrigued to note that the authors had omitted to mention the original report by Cohen & Cohen (1974) which had prompted Baastup *et al*, to conduct their review. Cohen & Cohen described four acutely agitated manic patients receiving the lithium and haloperidol combination who developed a toxic syndrome which they attributed to a specific haloperidol/lithium interaction.

However, Jefferson & Greist (1980) reviewed the original case reports and noted that the clinical descriptions resembled the neuroleptic malignant syndrome. This similarity has also been noted in other publications (e.g. Frankel & Spring, 1982). Since Cohen & Cohen's original paper, a number of other case reports have appeared in the literature, and other neuroleptics have been implicated in presumed toxic interactions with lithium. Having closely examined 26 similar reports of patients treated with haloperidol and lithium (Hone *et al*, 1985) we concluded that at least seven of the 26 met the criteria for the diagnosis of neuroleptic malignant syndrome, including the four patients originally reported by Cohen & Cohen.

In summary, we can find little or no support for the lithium/haloperidol interaction hypothesis. We consider that there is a need for a detailed epidemiological enquiry to identify the incidence of neurotoxic events resulting from the concomitant use of lithium and neuroleptics, together with other toxic sequelae related to neuroleptic usage. In conducting such a survey, we would hope to provide more information on these phenomena - be they attributable to lithium toxicity, drug interactions, or the neuroleptic malignant syndrome.

Anticholinergic Anti-Parkinson Medication for Neuroleptic-Induced Extrapyramidal Side Effects

Sir: We have recently received a piece of promotional literature entitled *Disipal in the Neuroleptic Syndrome*. The content of this document conveys a general impression that orphenadrine is a safe drug to use for the treatment of drug-induced extrapyramidal symptoms both in acute situations and for long term maintenance. We find the document biased and against all current scientific opinion on the subject and would like to counter some of the arguments presented in it.

Extrapyramidal side-effects frequently accompany neuroleptic treatment. In fact, anticholinergic agents used to reduce these symptoms are the commonest form of concurrent medication with neuroleptic therapy. There is, however, much debate about the adverse effects of combined therapy with these agents. It has been claimed that their use can result in exacerbation of psychosis, a delay in symptom improvement in patients with acute schizophrenia, and a predisposition to the development and/or deterioration of tardive dyskinesia. Many studies have reported that co-administration of anticholinergic drugs resulted in lower blood levels of neuroleptics. In others, although no differences were observed, combined therapy did have clinical implications (Bamrah *et al*, 1986). Clinically stable patients on neuroleptics do not normally show accompanying extrapyramidal symptoms except when dosages are increased or if extraneous factors lead to unpredictable increases in blood levels. As clinicians, therefore, we do not see the need for long-term medication especially if this is going to be associated with other interactions.

The document alleges that orphenadrine withdrawal may precipitate "a pronounced depressive state" in patients on combined haloperidol-orphenadrine therapy (Altamura *et al*, 1983). Whereas the relationship of depression with haloperidol is controversial, it is not unreasonable to assume that stopping a "mood elevating" drug could cause a rebound precipitation of dysphoric mood. One does not have to invoke "pharmacological interaction between orphenadrine and haloperidol leading to increased bioavailability of the latter" to explain this phenomenon. It seems to us irresponsible to elevate their "mood lightening" properties to

a position of clinical relevance since these are the very properties which may give them their drug-dependence potential.

These drugs have a powerful anticholinergic action which can summate with the anticholinergic action of neuroleptics to produce severe constipation or ileus, urinary hesitancy or retention, and intolerable dry mouth and blurring of vision (Lader, 1980). Besides, anticholinergics are themselves known to produce toxic psychoses (Shader & Greenblatt, 1971). Therefore, their use should be tempered with caution. Finally, if prescribed with abandon they would only provide the depressed patient with another means of self extermination.

We accept that the anticholinergic anti-Parkinsonian agents are valuable in clinical settings where it is necessary to relieve acute extrapyramidal symptoms following neuroleptic therapy, but we do not feel that the majority of patients require this treatment for more than three to four months. A literature review suggests that only a third of patients on maintenance treatment have any real need for this additional medication to control extrapyramidal symptoms, with the majority of surveys suggesting a substantially smaller proportion (Johnson, 1985).

Lithium Induced Hypothyroidism Presenting with Carpal Tunnel Syndrome

Sir: We describe a patient presenting with a recognised but unusual symptom of hypothyroidism which to our knowledge has not previously been reported in association with lithium.

Case Report: The patient was a 43 year old Kenyan Asian woman with a long-standing history of manic-depressive psychosis who had been treated with lithium for 10 years

At the out-patient clinic she gave a three month history of paraesthesiae in the hands, the right worse than the left, which woke her at night and were relieved by hanging her arms over the edge of the bed. There were no other symptoms of thyroid disorder. On physical examination pinprick and light touch were reduced over the median nerve distribution. There was a slight delay in ankle jerk relaxation and a smooth thyroid was easily palpable. Laboratory tests of thyroid function (which had been normal eighteen months previously) revealed total T4-12 nmol/L (NR 50-150), free T4-1 pmol/L (NR 10-28), TSH < 50 mU/l (NR 0-7 mU/l). Thyroid antibody screen was negative. Thyroxine replacement was instituted (100 ug daily) and after two to three months of treatment the symptoms of carpal tunnel syndrome resolved completely. Lithium was continued throughout.

Carpal tunnel syndrome may result from lithium therapy because of fluid retention caused by the drug. In this woman's case, however, the primary

cause must have been hypothyroidism because the symptoms resolved with thyroxine while lithium was continued. Several points are raised by this case. First, lithium induced hypothyroidism may present in unusual ways without typical symptoms such as lethargy, weight gain, voice change and cold intolerance. Secondly, hypothyroidism may present late—in this instance after 10 years therapy during which thyroid function had been normal on several occasions. Thirdly, the need for regular monitoring of thyroid function in patients taking lithium is clear (although a symptomatic presentation may still occur).

Book Reviews

The Oxford Companion to Medicine. Volume I. A-M. Volume II. N-Z. Edited by JOHN WALTON, PAUL B. BEESON and RONALD BODLEY SCOTT. Oxford: Oxford University Press. 1986. Pp 1534. £55.00.

That the egregious *Oxford Companion* series should be extended to medicine now seems inevitable and right, once it has been done, but this is in fact a completely new production, hard on the heels of that for literature. It is, by any standard, a formidable work—over 6000 entries, 1500 pages, 150 contributors, a £55 price, and two volumes: the Anglo-American 'special relationship' is seen in its full coverage of US institutions and practices and in the inclusion of American trade-names for drugs. Its purpose is described as to be "a comprehensive reference book, concerned with the theory, practice, and profession of medicine", and amongst the 150 major entries are psychiatry, covered by Michael Gelder, and psychology by the late H. Gwynne Jones; both are models of condensed information, elegantly expressed. Impeccable editing has ensured a remarkably uniform quality of excellence throughout the work of many disparate hands.

Since this is meant to be readable by the intelligent layman, detail on any topic is inevitably limited, but with few exceptions, practically any significant subject or person that one could think of will be found listed. Opinions will obviously differ about the amount of space appropriate for any one of them—hypnosis, for instance, might have deserved a much larger entry—perhaps at the expense of some parochial detail on institutions—and Sir Aubrey Lewis an item of his own. One of the most delightful sections is by A. M. Cooke on 'Doctors in Other Walks of Life (Medical Truants)' dealing with medical men as scientists, men of letters, churchmen, bibliophiles, linguists, missionaries, lawyers, philosophers, politicians, practitioners of the arts, and even criminals—including Dr Crippen, of course. However, Dr Mudd—who treated John Wilkes Booth after his assassination of Abraham Lincoln—seems to be missing. Some minor mistakes are inevitable in a work of this size, particularly in its first edition, and the entry on the Board of Control, for instance, records it as being still in existence, while the Mental Health Act Commission doesn't rate a separate item. This is clearly going to be an essential work of reference, and it is to be hoped that most libraries will be

able to afford it, even if few individuals can. It is a remarkable achievement.

HUGH FREEMAN, *Consultant Psychiatrist,*
Hope Hospital, Salford

After Hospital: A Study of Long-Term Psychiatric Patients in York. By KATHLEEN JONES. York: Department of Social Policy and Social Work, University of York. 1985. Pp 77. £3.50.

This booklet reports a survey of 150 patients discharged from mental hospitals in York over a two-year period. 50 were long-stay patients, predominantly schizophrenic, and 100 were elderly confused patients. They had been discharged to a variety of placements. The editor and her colleagues attempted to follow-up these patients, interviewing the patient or those involved in their care. They sought to answer four questions; what services the patients were receiving, how the necessary collaboration between agencies was working out in practice, to what extent discharge plans had in fact been implemented and whether the quality of patient's lives was adequate in their new situations. This information was obtained through freeflowing interviews given structure by checklists. It is apparent from the design of the study, which did not involve before-and-after comparisons or control groups, that no rigorous answers could be given to their questions. Nevertheless there is obvious value in the 'helicopter' view which the researchers intended to provide—the report certainly gives a very clear idea of the sorts of problems that arise from discharge and from a commitment to a policy of increasingly locating care in the community. The picture is augmented by the provision of case vignettes.

The success of discharging these patients was variable. Considerable care appears to have gone into planning the placement of the long-term patients, and some of these did very well. Less planning attended the discharge of the elderly confused and their success was likewise meagre. Individually, patients often showed both gains and losses as a result of their move. Collaboration between agencies about aftercare provision was found to be far from perfect.

In their summary, the authors emphasise that community care does not mean that a majority of

patients return to their homes. In any case, discharging patients to their relatives was sometimes neither humane nor cost effective. They point out that collaboration, often imperfect and often prescribed as a panacea for healing the defects of community care, is not cost free, and recommend the provision of permanent staff for Joint Care Planning Teams, and the establishment of a post of case-manager. More day hospital places and special provisions for the disruptive elderly patient are needed.

This report, while not over-enthusiastic, suggests that community care remains a feasible and humane possibility, but that if it is to be realised even in the benignant community of York, bolstered by its tradition of service and philanthropy, additional resources and deliberate management are required.

This book is of interest to all involved in managing chronic psychiatric patients in the community in the planning of services.

PAUL BEBBINGTON, *Honorary Senior Lecturer, MRC Social Psychiatry Unit, Institute of Psychiatry, London*

Mental Health Planning for One Billion People.

Edited by TSUNG-YI LIN and LEON EISENBERG.
London: University of British Columbia Press.
1985. Pp 232. £17.50.

There is currently great curiosity about all things Chinese. How do one quarter of the Earth's population live, in a country about the size of the U.S.A., separated from us by great distance, strange language, a culture and history which barely touched ours until the 19th century, and a political system which has rarely allowed free travel and reporting? There can be no doubt at all that under Chairman Mao and his successors medical care and the public health have taken an immense leap forward since 1949, but the details of what has happened, how precisely things stand now, and what further developments are practicable remain virtually unknowable, at least to Westerners.

There are so many difficulties. Some Marxist writers naively believe that alcoholism and mental disorders are due to oppressive capitalism and simply do not exist anymore in a socialist country. People fear loss of face, or criticism, or lack of patriotism if they admit the occurrence of suicide, for example. Diagnostic categories such as neurasthenia or depression may be used differently, not defined and without clear consensus. China does not publish any reliable national statistics of the incidence of mental illnesses or psychiatric behaviours, or of the distribution of hospitals or professional workers, and one

recalls there are about 20 provinces of ethnic and geographical diversity and some autonomy in health matters.

There is no unified standard health service. In the present book Professor Liu Shie-Jie writes (p. 89) "Two parallel health care systems exist and function side by side... For example, the Capital Steel and Iron company has its own health department, which administers its own hospital and health station... and in addition has clinics in various small factories... under the supervision of the Ministry of Metallurgical Industry, not the Ministry of Health." Under the latter's umbrella there are independent special services for tuberculosis, drug control, maternity etc., and also provision of hospitals and/or clinics by provinces, cities, counties, districts, communes and brigades, administered locally with local finance. It cannot with such diversity be easy to collect information to give a clear factual picture of the working of mental health services in one city, let alone one province. There are beginning to be a few very careful small scale studies such as that reported in this book by Xiang Mengze on a survey of neurosis among general hospital patients in one county hospital in Sichuan (population 100 million).

This book consists largely of papers presented at two 1983 Beijing conferences on Psychosocial Aspects of Primary Mental Health Care, and a third of it deals with children. Its title is misleading. Planning a mental health service involves knowing what illnesses are frequent, what customers want, and what health workers, training, buildings, money are available, or could be, to meet the challenges. This book is not about such matters. Inevitably it contains much more about what might be than what is. But it does introduce us in an elementary way to 36 years of history and to mental health work in one or two places. Where there is so little information this is a beginning to be welcomed.

JOHN CRAMMER, *Reader Emeritus in Biological Psychiatry, Institute of Psychiatry, London*

The Anatomy of Madness. Essays in the History of Psychiatry. Vol I. People and Ideas. Pp 316. Vol II. Institutions and Society. Pp 283. Edited by W. F. BYNUM, ROY PORTER and MICHAEL SHEPHERD. London: Tavistock Publications. 1985. £19.95 each.

These two volumes of essays on the history of psychiatry are for me the best literary lucky-dip to come my way for many a moon. As in all lucky-dips, however, the prizes vary in value; but there is not one

here which is not well worth having. It says a lot, incidentally, for the catholicity and fair-mindedness of the editors (and of the organisers of the seminars during which most of the essays were read), that they allowed, not only such a diversity of views to be expressed, but also allowed one contributor to do battle with another.

As an excellent example of the former I would cite Anthony Clare's, 'Freud's Cases: the Clinical Basis of Psychoanalysis', a courageous exposé of the lack of scientific evidence to support any claim for therapeutic benefit in psychoanalysis, a conclusion which must have raised the hackles of his psychoanalytically orientated co-contributors.

And as an example of the latter, I would commend 'Bedlam: Fact or Fantasy?', by the redoubtable Patricia Alderidge, Archivist to the Bethlem Royal Hospital, in which she fights like a tigress in defence of her hospital. She attacks those historians, and in particular Andrew Scull, for perpetuating the myths of brutality, corruption and exploitation which have tarnished Bethlem's good name for centuries.

But if Andrew Scull is floored in this particular encounter with Patricia Alderidge, he lives to fight another day. Indeed, his contribution, 'A Victorian Alienist: John Conolly', is one of the major prizes on offer. His, as far as I am aware, is the only study in any depth of this folk-hero of British psychiatry, and it is saddening, in a way, to learn that, great as he undoubtedly was, Conolly like any other man, had feet of clay.

For idolaters in psychiatry, it is equally disconcerting, to read in Anne Digby's, 'Moral Treatment at The Retreat, 1796-1846', that patient care at The Retreat wasn't always all it has been cracked up to be. She ends her essay on an enigmatic note, "This poses the fascinating but unresolvable question of whether the distinctively religious character of The Retreat's moral treatment did not rely for its efficacy, at least in part, on an unseen kernel of spiritual healing".

It would be invidious to attempt to place the other essays in any sort of rank order, but one of the top prizes must go to Ian Dowbiggin's, 'Degeneration and Hereditarianism in French Mental Medicine 1840-1890: Psychiatric Theory as Ideological Adaptation'. This is the period in French psychiatry dominated by Doctors F. J. Moreau and B. A. Morel, and a period too, when the reputation of psychiatry and psychiatrists had hit rock-bottom. Dowbiggin's well argued thesis is that "It is undeniable that this scientific milieu after the mid-century made the theory of morbid heredity all the more acceptable as a way of improving psychiatry's desperately poor image and neutralising public enmity,

while it helped to heal the divisions within the professional community". Nevertheless, it should be noted that, despite the ethical dubiety of its origins, there can be no doubt that the theory of morbid heredity profoundly influenced the thinking of contemporary British psychiatrists, and in particular, that of Henry Maudsley.

Martin Stone's, 'Shellshock and the Psychologists', is also prize worthy and earns a bonus for reminding us of the finest examples of muscular jingoism ever pronounced. This pearl is attributed to Sir Robert Armstrong-Jones, quondam president of the Medico-Psychological Association and a bitter opponent of what he termed, "Freudism". At a meeting of the Society in 1920 he declared that psychoanalysis was, "probably applicable to people on the Austrian and German frontiers, but not to virile, sport-loving, open-air people like the British". Beat that, you cad!

HENRY R. ROLLIN, *Emeritus Consultant Psychiatrist, Horton Hospital, Epsom, Surrey*

An Introduction to the Borderline Conditions. By WILLIAM GOLDSTEIN. Northvale, New Jersey: Jason Aronson. 1985. Pp 241. \$25.00.

The concept of "borderline" psychic functioning has been employed in psychoanalysis for half a century. Now after increasing usage recently in general psychiatry, the term has obtained formal recognition through the inclusion in DSM-III of the category "borderline personality disorder". Unfortunately, although the psychoanalytic and descriptive uses of the term apply to similar entities, there are troublesome difficulties in emphasis. Nosologically the term has been used to describe a cluster of symptoms and traits which define a diagnostic category, *the borderline personality*. Psychoanalytically the term refers to a hypothetical psychic configuration and related pattern of mental functioning, and is used diagnostically only as a supraordinate concept to differentiate *the borderline conditions* from neurosis and psychosis. This situation is a recipe for misunderstanding and conflict, dynamics which are all too prevalent in work with this difficult group of patients.

Any book which provides "an in-depth yet simplified understanding of the different uses of the term today" would be welcome indeed. Unfortunately Dr. Goldstein does not succeed wholly in his stated aim. He offers breadth at the expense of depth and simplicity.

A psychiatrist and psychoanalyst Dr Goldstein approaches the subject from the standpoint of

ego-psychology, a useful framework both for describing the characteristic structural configuration which underlies the typical symptom cluster, and for establishing a *psychodynamic* diagnosis of borderline personality organisation. He details the history and current psychoanalytic application of the concept, and outlines both the discriminant studies which defined the "borderline personality disorder" and its clinical features. There is a useful chapter describing the influential work of Kernberg, though this overview is repetitive and lacks depth. For some reason a comparable overview of Kohut's work is assigned to the section on differential diagnosis, where an exploration of the relationship between borderline and narcissistic disorders serves to confuse rather than simplify this complex field.

The section on treatment strategies includes some illustrative case studies and a useful brief overview of psychotherapeutic approaches; but it concludes with an unbalanced review of the modifications to psychoanalytic technique which have been applied in the treatment of borderline patients. This chapter captures the dilemma of this book, the conflict between Dr Goldstein's attempts to simplify the subject for the general reader and his extensive coverage of the analytic literature on the psychopathology and treatment of the borderline conditions. There are some valuable nuggets to be found here for everyone, but there is much waste too. A book for the library perhaps.

MIKE HOBBS, *Consultant Psychotherapist,
Warneford Hospital, Oxford*

International Handbook of Behavior Modification and Therapy. Student edition. Edited by ALAN S. BELLACK, MICHEL HERSEN and ALAN E. KAZDIN. New York: Plenum. 1985. Pp 471. \$24.95.

This book is an abbreviated, but not an up-dated reprint of the 1982 *International Handbook of Behavior Modification and Therapy*. It comprises thirteen complete reprints of the more than twenty chapters in the original edition: One chapter now being devoted to the history of behaviour therapy, three to methodology, five to adult and four to childhood disorders.

In 1982, the widely acclaimed original edition was an impressive comprehension of the development of the whole field of behaviour-modification and -therapy. But, it did not have a special focus on clinically relevant research, and thus included extensive reviews of literature which was more historically important than clinically meaningful.

This 1985 reprint is certainly not the "representative curriculum for an introductory graduate seminar on behaviour therapy", that the editors would like it to be. The graduate student of behaviour therapy—regardless whether from a medical, psychological or nursing background—can best be motivated for active learning by vivid, treatment-relevant materials (of course, with a historical perspective). And here in particular are the shortcomings of both editions.

For the student as well as for the clinician, since 1982 several better suited books have appeared, additionally to the well-known annuals *Progress in Behavior Modification* and *Annual Review of Behavior Therapy*. They all cover the same or very similar topics to be found in this reprint. Among these, the *Handbook of Clinical Behavior Therapy with Adults*, with main emphasis on "what experienced clinicians actually do with their patients", also appeared in 1985, and it is also edited by Hersen and Bellack (two of the three editors of the 1985 reprint).

Covering the literature only until about 1980, the 1985 reprint misses such important new developments like: long-term follow-up studies and the "panic" controversy in treatment of phobias and other anxiety disorders; "medication versus behaviour therapy" research in depression and obsessive-compulsive neurosis; recent behavioural-psychological approaches to addictive behaviours and their relapses; new developments in couple and family interventions—including the systematic, *in-vivo* family treatments for schizophrenics, now available; benefits and risks from the increasingly popular self-help manuals for a wide variety of problems and disturbances; research into "failures in behaviour therapy"; and, last but not least, the general "strategy" of clinical behaviour therapy as the essential framework for the application of its techniques and procedures.

For the teacher in (clinical) behaviour therapy, this low priced reprint is by no means a substitute for the efforts and the rewards of a carefully selected and regularly updated reading list for his students. For the research worker, the experienced clinician and the librarian, a low priced sale of the original edition, at least to some extent, would have been a substitute for a revised complete edition.

IVER HAND, *Professor of Psychiatry,
Hamburg University Clinic*

Handbook of Intelligence: Theories, Measurements and Applications. Edited by BENJAMIN B. WOLMAN. Chichester: John Wiley. 1985. Pp 985. £66 45.

Handbook of Intelligence is a solid American piece of work in several senses. It is written in grammatically

correct academic style, and its thousand pages are very well edited. The inside cover describes it as being written by "leading international authorities", though only a single non-American chapter out of the 23, seems to have merited that accolade, and almost all references are to American work. Maybe they mean inter-state, as in the World Series baseball league. No other book, it claims, has "examined intelligence with the depth and breadth of this work", and for sure there is plenty of it, yet there is no reference to personality vis-à-vis intelligence in the limited subject index, and creativity is only considered as a minor aspect of giftedness. How can the publishers justify the price?

However, there are some gems within. Robert Sternberg's chapter explaining his thesis on the relationships between cognition and intelligence is scholarly, thought-provoking, and valuable; he describes how psychometric and cognitive theories complement and enhance one another, and proposes an ideographic approach to human abilities. Nathan Brody argues well from evidence that what most of us understand by intelligence is about right, and that the tests do measure it validly. But in direct contradiction, Michael Lewis and Margaret Wolan Sullivan, in their excellent survey of infant testing, stress that intelligence cannot be unitary, and see the IQ as a tool of social control.

The overview chapter on the neurological foundations of intelligence is useful, though the writer's assumption that 'g' with its subsidiaries describes intelligence is somewhat simplistic. But then, John Horn in his elegant piece on models of intelligence, finds the idea of 'g' "almost certainly incorrect and not very useful". Another contributor provides statistical evidence that intelligence is polygenic. Guilford and his cube of 120 potentially distinguishable abilities take a bow. His system, he says, is the first to detail the functioning of intelligence on a scientific foundation, and he suggests that teachers should plan their lessons round it.

The Max Planck team follow a developmental, life-span perspective of intelligence, focussing on adulthood, and distinguishing between its practical and cognitive aspects. Looking at research findings, they conclude that plasticity is paramount in the first part of life, giving way to multidirectionality and multidimensionality within the wider experience of adulthood. Adequate coverage is given to environment in IQ, the history of testing, clinical assessment, including some pertinent comments on assessing minorities, and to group and individual testing. The chapter on giftedness is poor.

Intelligence to the psychologist is like schizophrenia to the psychiatrist. I quote one of the con-

tributors—"The nature of intelligence is a highly complex issue", and a psychiatrist at a recent meeting on schizophrenia—"it is very difficult to understand".

JOAN FREEMAN, *Honorary Tutor, Department of Education, University of Manchester*

Guide to the Use of Psychotropic Drugs. By DONALD GILLIES and MALCOLM LADER. Edinburgh: Churchill Livingstone. 1986 Pp 532. £14 95.

This book is primarily addressed to pharmacists. With the current proposals to encourage a greater advisory role for community pharmacists it is important that they have a broad understanding of psychiatry as well as possessing a sound working knowledge of psychotropic drugs. The book is divided into three unequal parts. The first deals with psychiatric conditions, the second with drug usage and therapy, while the third, much the largest, partly lists alphabetically all the psychotropic drugs in current usage, providing relevant information about each.

The first section which takes the form of an elementary introduction to clinical practice is a model of its kind. All the major psychiatric conditions are described with helpful notes on aetiology and management. I did, however, think it unfortunate to state that schizophrenia was an illness for which "there is an increased representation of lower social classes..." this implies causation rather than consequence. Despite such occasional blemishes I would wholeheartedly commend this section to any non-clinician looking for a succinct up to date introduction to psychiatry.

The next section can be best described as an introduction to clinical psychopharmacology. In my opinion this is rather too terse. A general brief description of synaptic transmission and the sites of action of psychotropic drugs would have been helpful. There are three main categories of drugs considered (antipsychotic, antidepressant and anti-anxiety drugs) plus lithium and "miscellaneous". One objection in this section: I cavill at the collective term tricyclic antidepressants; the tricyclic structure is not exclusive to antidepressants, nor does it include all non MAOI antidepressants. Another quibble, pimozone is not really very closely related to haloperidol, and being a much more selective dopamine receptor blocker is less likely to cause drowsiness and to promote weight gain.

The third section which takes up 470 of the 532 pages takes the form of a psychotropic mini-Martindale. There is a great deal of repetition. For example the mode of action of the monoamine

re-uptake antidepressants is solemnly repeated word for word for each drug in this category. The same is true for side effects. Without such repetitions the book could be made much slimmer.

At the end one is left with the question: What advantage for pharmacists does this book have over the National Formulary, a regularly updated work which is widely distributed by the DHSS? There are two. Firstly it is an advantage to have the relevant pharmaceutical information placed in a clinical context; secondly it must be more convenient for pharmacists working in a psychiatric setting, as well as for students of pharmacy to have all the psychotropic drugs placed together. In addition it would be a useful reference work for nurses on psychiatric wards.

TREVOR SILVERSTONE, *Professor of Human Psychopharmacology, German Hospital, London*

Mind, Brain, Body: Toward a Convergence of Psychoanalysis and Neurobiology. By MORTON F. REISER. London: Harper & Row. 1986. Pp 228. £17.50.

Psychoanalysis and neurobiology occupy different domains with different conceptual languages, and the relationship between them can seem obscure. Can they have anything to say to each other? Reiser believes so. He describes a hypothetical situation of a popular baseball match being shown on TV. As one team scores, three overweight middle-aged supporters of the losing team die of a heart attack. On the other hand, if the other team had scored, three different men might have died. The physical stimuli are the same in each case; only the meaning is different. The question is 'How is input at the level of meaning transduced into a physiological reaction?'.

Reiser draws on raw data from his own clinical psychoanalytic practice, to illustrate processing at the level of meaning. Describing two successful analytic treatments, he diagrams the complex network of ideas, memories and fantasies. He stresses the complexity of memory processes in the patient, in the analyst, and in the interaction between. For example, the patient's description of the onset of a recent phobia prompted a memory *in the analyst* of a dream from an earlier period of the treatment. Drawing attention to this dream led to recognition of the meaning of the phobia, with immediate symptom relief. Reiser notes that "case reports which deal only with the process in the analysand may be recording only one part—a solo version—of what is really a two part play—a duet".

In going on to discuss psychosomatic states, Reiser outlines some of the complex feedback systems

involving different areas of the brain at higher and lower levels, and the endocrine system. He takes anorexia nervosa as an example of a syndrome which demonstrates how social and cultural influences interact with psychological and biological processes. Emphasizing that the brain should be regarded as part of the body, he suggests that schizophrenic and affective disorders could be understood as stress disorders in which the brain is the target organ. These syndromes may begin with disturbance at the level of meaning, which may be conveyed in language, but once such a syndrome is fully developed, it may become therapeutically beyond the reach of words alone. This clearly has implications for the linking of verbal psychotherapy and psychopharmacological approaches.

There are many interesting and original ideas in this book, but overall I found it unsatisfying, seeming to promise more than it delivers. Despite Reiser's avowed aim of demonstrating points of contact between the disciplines, these possible links and their implications seem insufficiently elaborated.

PHIL MOLLON, *Psychologist, Dryden Road Hospital, Tyne and Wear*

The Frontal Lobes. By DONALD T. STUSS and FRANK D. BENSON. New York: Raven Press. 1986. Pp 303. \$65.50.

It is of interest that the frontal lobes, estimated to cover around one third of the total cortical surface of man, remains an enigma. We seem to know far less about the frontal lobes than other areas of the brain, although reports of disturbances of behaviour following damage to the frontal cortex have been recorded for over a century. These regions, in addition to other new well described areas of the brain, compromise association cortex, areas we now know that are intricately involved with higher cortical function in contrast to their presumed redundancy of early theorists who thought of them as silent areas.

This comprehensive review of the frontal lobes will come with great relief to clinicians who wish to grapple with some of the more important aspects of frontal lobes structure and function in relationship to their discipline, being succinctly written and timely in the sense that the frontal lobes have once again recently become of great interest to people of different disciplines, but in particular neuro-psychiatrists. Thus, the clear delineation of frontal lobe syndromes, alongside other neurophysiological abnormalities that occur secondary to focal damage, has

been important for the growth of behavioural neurology, and techniques for monitoring the frontal lobes and frontal lobe function have become more readily available recently with such technology as MRI and PET scans.

The book initially outlines neuroanatomical and neuropathological considerations, and then provides an overview of the methodology for monitoring frontal lobe activity both experimentally and clinically. Disorders which involve frontal lobe function are considered, and these authors raise the possibility that frontal lobe function not only is associated with the well known frontal lobe syndrome, but is also abnormal in such conditions as the Capgras syndrome, reduplicative paramnesia and a confabulation.

Frontal lobe abnormalities in more purely psychiatric syndromes such as schizophrenia and depressive illness do not receive much attention, in spite of the considerable evidence that now exists showing that at least a sub-group of patients with schizophrenia have clearly demarcated abnormalities of frontal lobe function. Nonetheless, psychiatrists who wish to familiarise themselves with the complexities of frontal lobe influence over other neuronal systems, and the most appropriate ways to detect frontal lobe dysfunction clinically will gain considerably from reading this book.

Finally, the authors give their own theory of frontal lobe function, after reviewing those of others. The essence of it is based upon a hierarchical division of frontal lobe functions controlling other systems. The "pre-frontal cortex attends, integrates, formulates, executes, monitors, modifies, and judges all nervous activities", but further is also intimately involved in self-awareness and self-consciousness. Whether or not one accepts such a view, the fact that all those who have studied the frontal lobes believe that they are involved in man's highest cognitive functions and are related to the organisation and planning of behaviour would mean that they become a natural subject for study by all psychiatrists. This book is recommended as an excellent volume for anyone's library.

MICHAEL R. TRIMBLE, *Consultant Physician in Psychological Medicine, The National Hospital for Nervous Diseases*

The Father: Contemporary Jungian Perspectives.

Edited by ANDREW SAMUELS. London: Free Association Books. 1985. Pp 266. £22.50 (hb), £8.95 (pb).

Except for one Freudian paper, this book is a collection of papers on or relevant to the actual father and

the father-archetype by Jungian analysts. Several of these are trying to begin to remedy the dearth of psycho-analytic writing on the role of the father in personality development. Samuels feels that in the past decade or two the patriarchal castrating he-man, if he ever existed, has given way to the kinder, loving, sensitive father. Although basically a positive change, the 'new' father may be unhappy because he has not freed himself sufficiently from the mother, so we still have an unbalanced situation. A paper by David Kay describes a patient whose father had mothered or indeed over-mothered him for his first six months of life, and then left him to go away on business. There were difficulties in establishing a personal identity and gender confusion which (on the evidence of the changes in the analysis) were the result of these early passionate experiences with this unusual father. As I happened to have had this father in therapy I can vouch for Kay's completely accurate reconstruction of what the father was like from Kay's transference/countertransference emotions with the son and their evolution during analysis. For example, Kay says "For a man who has serious doubts and confusion about his sexual identity and potency, the arrival of an infant, particularly a first-born beautiful male child, can have a very powerful and crucial effect. The father, in the example quoted, saw and experienced his son as the 'Divine child hero'—living proof that his self doubts were at an end." When I saw the father in therapy thirty years later he was deeply involved in one more of several relationships of identical nature with boys and young men, on to each of whom in turn had been projected this same semi-divine image. It is a very comforting validation of modern analytical technique and of Kay's skill in particular that Kay had reconstructed the feeling of this patient's early relationship with his father so accurately.

In another excellent clinical paper Eva Seligman describes a series of 'half-alive' patients for whom the father had been in some sense absent, and therefore unable to help the patient free himself from a mutually collusive embrace with the mother which had nourished an illusory 'one-ness' with her.

John Beebe contributes a thoughtful article about the effect of the father's emotional attitude towards his son on the son's psychology and destiny. Andrew Samuels' article on 'The image of the parents in bed' discusses the primal scene both in terms of how the infant experiences the parent relationship and how he projects the archaic, archetypal parental images. He hypothesizes that his images of two-ness (first mother and baby, then the parents together) create a climate in which images of three-ness can begin to exist and the paternal image can emerge. Allenby's

paper on father fixation balances Layland's on the need of a loving father. There are three further articles mainly on the archetypal aspects of the child-father relationship, including Jung's seminal paper originally written in 1909.

I think that bringing these papers together in one volume, with the valuable linking explanations of the main introduction and the subsidiary introductions to each paper, was a very worthwhile undertaking for which Samuels deserves credit. In this book the father comes to life as a whole human being in analytical theory.

J. W. T. REDFEARN, *Director of Training,
Society of Analytical Psychology, London*

The Nightmare: The Psychology and Biology of Terrifying Dreams. By ERNEST HARTMANN. London: Harper & Row. 1986. Pp 294. £16.95.

Ernest Hartmann is both a psychoanalyst and a leading American sleep researcher. This book, the fruit of many years research in both fields, demonstrates an exemplary integration of clinical insight and experimental data, the results of which have important implications well beyond the specific phenomenon of terrifying dreams.

Hartmann distinguishes between three separate conditions which have often been grouped together under the single heading "Nightmare". These are 'ordinary' or typical nightmares, post-traumatic nightmares and night terrors. The major research concerns a group of lifelong sufferers of 'ordinary' nightmares. On the basis of several comprehensive studies he proposes the concept of "thin boundaries" as the essential characteristic shared by these people, i.e. they have a strong tendency to blur the distinctions between different categories of experience such as sleeping vs. waking, fantasy vs. reality or self vs. other. Hartmann is at pains to consider the non-pathological indications of these findings alongside the pathological ones. Thus, while such people are unusually defenceless, open and vulnerable and this may constitute a susceptibility to schizophrenia, thin boundaries may also be an advantage in both artistic and scientific endeavour.

Although hardly conclusive, the evidence which he has accumulated in this area is a valuable contribution towards understanding the link between creativity and madness.

The remainder of the book concerns clinical and biological aspects of the nightmare. Nightmares are interpreted as expressions of basic childhood fears, especially of helplessness and catastrophic loss. Post-traumatic nightmares occur when these fears

have been realised but only in circumstances where mental boundaries are unusually vulnerable. Normally, these nightmares gradually become integrated with ordinary dream material but in extreme cases the traumatic memory becomes encapsulated and can be "set off" by a variety of physiological or emotional disturbances.

The biology of the nightmare is thought to involve an increase in dopaminergic activity at the forebrain. Hartmann hopes that further investigations might lead to the establishment of a biological basis to the concept of mental boundaries. If so, an important bridge between biology and psychology will have been created.

WARREN COLEMAN, *Psychotherapist,
Institute of Marital Studies, London*

The Provision of Mental Health Services in Britain: The Way Ahead. Edited by GREG WILKINSON and HUGH FREEMAN. The Royal College of Psychiatrists: London. 1986. Pp 197. £7.50.

This volume brings together the contributions of twenty speakers and the edited discussions of a conference organised by the College and the DHSS.

The editors' introduction draws comparisons with a similar conference in 1972. At that time informal and piecemeal developments in district psychiatric services were being embodied in government policy. The present volume illustrates something of the scope of subsequent change and obstacles to future development. The contributions range from a few blandly hopeful restatements of policy, which suggest that with more resources, flexibility, leadership and teamwork all will be well, to the hackneyed criticisms of mental hospital closure. Between these extremes there are reasoned appreciations of the inevitable difficulties and dangers of change. There is, for example, an interesting analysis of the differing structures and organisation of Health Services and Social Services and how these impede continuity of care.

Old age psychiatry and services for the mentally handicapped are well covered, while the views of consumers and those in disciplines other than psychiatry receive attention, but less space.

As in most recent accounts of change in psychiatric services, one detects an uneasy and rather reluctant acceptance of proposed developments. There are anxieties about the rhetoric and the wishful thinking, and how, with the decentralisation of services and the dispersion of responsibility, it will be possible to maintain control of policy. There are doubts too about the difficulty of joint planning and financing and the inevitable queries about cost.

Excellent services in many parts of the country still have serious gaps. Progress is slow and "the sheer inertia of mind and matter" which Enoch Powell foresaw, has not yet been overcome. Since history has no ready-made answers for us, our slow advance gives us time to follow the innovations and to avoid some of the pitfalls which this book describes.

DOUGLAS BENNETT, *Emeritus Physician,
Bethlem Royal and Maudsley Hospital, London*

Therapeutic Factors in Group Psychotherapy. By SIDNEY BLOCH and ERIC CROUCH. Oxford: Oxford University Press. 1985. Pp 342. £16.00.

Group psychotherapy is well established as a treatment mode in modern psychiatric practice. Once regarded as the poor relation of individual psychotherapy, the experiences of those involved in the Northfield Military Hospital work during World War II led to increasing recognition of group therapy as a powerful tool in its own right, and a body of theory developed with various 'schools' promoting their particular approaches. Therapeutic communities represent one aspect of applied group therapy, but ignorance of group dynamics may limit both the potential and the effectiveness of in-patient units and day services alike, whereas their exploitation offers well-recognized benefits in many forms of treatment.

Although many of the benefits of group therapy have been recognized clinically, and therefore become enshrined in practice, the actual way in which group psychotherapy works remains poorly understood. A considerable body of research work has been published, much of it in the U.S.A. but too often studies have been badly designed or carried out on experimental volunteer populations, so that extrapolation of the findings has contributed little to our understanding of group psychotherapy with patients.

Therapeutic Factors in Group Psychotherapy is a most welcome and long overdue addition to the literature in this field. The authors have reviewed systematic research in group psychotherapy over the past thirty years, and have assembled the knowledge that has emerged on how and why group therapy works, setting out to dispel the vagueness generally associated with this subject. In the first chapter they consider the important matters of definition and classification, leading to their own selection of ten therapeutic factors and the methods which have been used to study them. Subsequent chapters are devoted to each therapeutic factor in turn, with definition, theoretical aspects and empirical research covered in detail, and a comprehensive list of references. The

final chapters deal with therapeutic factors overall, their relative neglect, their importance, and the prospects for their future study. A useful appendix of experimental research setting out the findings of cited studies in tabular form, and separate author and subject indexing ensures that this book is easily accessible for reference by prospective researchers and all who seek to become better informed about group psychotherapy.

At a mere £16.00 for a well-printed text in hard covers, this book is a real bargain. It should be available in every psychiatric library, and recommended reading for all who use groups in the course of their work. Trainees embarking on group psychotherapy for the first time, as well as experienced therapists whose clinical knowledge is unlikely to be equalled by their researches in the field, will find much food for thought in this readable book, which may well serve to stimulate group therapists into more and better therapeutic factor research with patient groups. The authors have distilled their subject matter into a compact volume which is likely to be an important source of reference for the next decade; it is one for all group therapists to buy and consult.

PAMELA ASHURST, *Consultant Psychotherapist,
Royal South Hants Hospital, Southampton*

Prediction in Criminology. Edited by DAVID P. FARRINGTON and ROGER TARLING. New York: State University of New York. 1985. Pp 278. \$39.50 (hb), \$14.95 (pb).

This is mainly a book for criminologists and those others who are both interested in telling the future and well versed in the nomenclature and methods of statistics. In addition to British contributors there are several from the USA and one from Canada. The predictions covered include recidivism, absconding, and risk and failure among parolees. There is a very interesting chapter on 'The Politics of Prediction' which highlights the folly of the doctrine that taking specific action against individual offenders has an influence on crime in general. Throughout the book a blindingly obvious theme recurs: that predictor variables will never be refined until the criterion variables of, for example recidivism, are something more than simply reconviction and the type of offence committed.

There are two chapters for the psychiatrist. The first looks at self injury in a population of female Borstal detainees, several variables were found to discriminate well between self-injurers and non-injurers but they were clearly independent: a history of psychiatric treatment, institutional experience, self-injury; high scores on neuroticism and aggression, low scores on happiness and self-esteem. In a prospective study these and other variables combined to form a risk rating which accurately predicted 83% of all self injurers.

The second chapter of interest is from Broadmoor Hospital's Psychology Department. It describes a cohort of

discharged patients studied retrospectively and claims to be the first work of its kind to use data collated from clinical assessment. The authors express the hope that developing their method will lead to the application of empirically validated criteria to patients under consideration for discharge and to the evaluation of treatment programmes. But the authors do little to temper the pessimism which surrounds predictive research in the psychology and psychiatry of dangerousness and there is little new in their showing that previous convictions, previous psychiatric admissions and types of offences were most highly related to the four outcome measures: committed further assaults, subsequent court appearances, re-admission to Broadmoor, and not remaining in the community for the entire five year follow-up.

The Broadmoor study does make a plea for discrimination between the treatment needs of patients. It emphasises the lunacy of treating over-controlled homicidal offenders who are so inhibited that they have no behaviour, other than the catastrophic, for coping with stress alongside undercontrolled offenders who need to increase these same inhibitions.
